When rolls are set CLOSE, *i.e.*, face to face, the only way that material can pass through is for it to force them apart. Observation shows that this spreading is intermittent, so that a longitudinal section of the ribbon is a succession of lenses (Fig. 48, item *a*), which are more closely spaced the more heavily the rolls are fed. The maximum spread must equal at least the thickness of the thickest (usually the largest) particle in the product. If the linear sections of the stream, *i.e.*, the spacings between lenses, are assumed to be reduced to a series of points (Fig. 48, item *b*), and these are considered as a series of apex-connected rhombs (Fig. 48, item *c*), the equivalent ribbon of uniform section would be one having a thickness equal to one-half the maximum roll spread. Assuming a shape factor of 1.7, the minimum mean roll spacing or apparent set is 0.3 times the aperture of the circuit-closing screen.

a *b* *c*

FIG. 48. Longitudinal section of ribbon in close-set rolls.

Reduction capacity for rolls differs greatly according to size and to method of feeding. Table 24 indicates that in free-crushing, with a reduction ratio (R_{80}) between 1.5 and 2, the average capacity of 30-in. rolls is about 15 reduction t.p.h.; for 36-in. rolls, 20 reduction

tons; for diameters in the 40's, 45 reduction tons; in the 50's and 60's, 150; and in the 70's, 450. In choke-crushing, with reduction ratios averaging 5.0, the corresponding capacities are: 30's, 30 reduction tons; 36's, 150; 40's to 60's, 250 to 300; 70's, 1,200 to 1,500. It should be noted further that the large heavy-duty rolls may be and are frequently operated at reduction ratios up to 20 or 25, with choke-feeding and heavy circulating loads, and that under these circumstances the capacities in reduction tons of the rolls in the 40 to 60-in. range increase above the averages given above in proportion to the increase in reduction ratio. Whether the reduction capacity of the 72- and 78-in. sizes can be similarly increased is not certain on the basis of the data available, but it is probable.

Motors recommended by roll manufacturers are almost invariably oversize; the roll is thus overpowered in order to provide for overcoming incipient chokes for whatever cause, and to facilitate cold starting. Motors should, therefore, be of types which show high efficiencies at underloads (see Sec. 20, Art. 7).

Efficiencies of rolls, expressed as reduction tons per hp-hr., are dependent primarily on whether the operation is free- or choke-crushing; size of machine has an effect, and it is probable that character of rock is also a factor, but if so, it is not a large one. Efficiencies in free crushing average from 0.5 to 1.1 or 1.2 reduction tons per hp-hr. for smaller rolls and up to 2.2 in the larger machines; in choke crushing the average is from 6 to 7, with some extra heavy duty figures running up to 10 or 12. Efficiency increases with weight of the revolving parts, and with speed up to the point of nip failure, owing to the magnitude of the resulting inertia effects and the consequent leveling off of peaks in the power draft.

Feeding. Rolls must be fed at a constant rate and with the stream distributed over the full width of face in order to get maximum capacity and efficiency. If the feed stream is not distributed over the full face, circumferential grooving occurs under the feed point and the amount of crushing done at one pass decreases rapidly. If the feed is not constant in quantity but comes in surges or rushes, the rolls are liable to choke and stall or, if the driving equipment is sufficiently heavy to prevent this, they spring apart and pass a mass of material only partially crushed. This causes chattering and excessive wear on slides and babbitt; it produces a greater tonnage of circulating feed, if the rolls are run in closed circuit with a screen; and makes it impossible to reach maximum capacity. Present best practice is to use surge bins of 15-min. to several hours' storage capacity, delivering through constant-rate feeders.

At International Nickel Co., feed rate is manually controlled by the operator, who varies the speed of a pulley feeder so as to feed to the full limit of motor capacity; if the hardness of the ore varies, feed must be varied accordingly.

Transfer from feeder discharge into the roll housing is made by a spout. This spout should be flat-bottomed, transversely level, of the same width as the roll face, so placed that the transverse level line is parallel to the axes of the roll shafts, terminated so that the trajectory of the falling material is into the bottom of the vee between the rolls, and that the speed of the stream making contact with the roll faces is substantially that of the faces themselves. The aim is to bring a roughly rectangular stream of material into the crushing zone at such a speed that slipping between particles and roll faces is minimized. If the feed spout, properly made and set, will not deliver such a stream, rods or other distributing devices, placed to suit the problem, should be installed. If the cheek plates are moved back sufficiently to permit a small amount of spill at the edges of the rolls, edge flanging is diminished materially and operation is more efficient despite some tramp oversize in the product. If the feed contains a large percentage of clayey material, rolls are liable to choke.

Rolls may be free-fed or choke-fed, the former phrase indicating freedom of movement between particles resting in the vee of the rolls prior to nipping, the latter that the particles at this point are piled up to such a depth that no free movement exists. In free-feeding, each particle is broken substantially individually and crushing is practically uniform and continuous; in choke-feeding, masses of material are rolled through intermittently, the roll faces springing apart to permit their passage. In this compression of the mass of rock there is much abrasion between particles which results in a less granular product than that from free-crushing. Except in the case of the largest rolls, choke-feeding can be practiced only with material already crushed to 1/4-in. or less.

Rolls are ordinarily run dry. Wet feed aids nipping and prevents dusting, but increases maintenance costs.

Open-circuit feed. It was found at Consolidated M. & S. Co. (*61 CMJ 495*) that retention of a certain amount of fines in the scalped feed to open-circuit rolls made for quieter operation (less jumping) and correspondingly less oversize in product. On the other hand, when crowding the rolls, too much fine material in feed exceeded their capacity and stalling occurred. Crowning the feed shute, thus tending to equalize distribution of feed, tended to reduce corrugation.

Closed circuit means that the product of a crusher or grinding machine is sent to a sizing device which permits undersize only to discharge from the circuit and returns oversize for further crushing. As a result of such practice a circulating load, comprising such returned material, builds up gradually until it reaches a constant tonnage, assuming constancy of operation. Circulating load is ordinarily expressed as a percentage of the new feed and normally ranges in roll circuits from 75 to 400%; it is smaller in coarse crushing than in fine, small when the ratio of aperture of closing screen to roll set is relatively large (upward of 4 : 1), small when screening is efficient; it increases with moisture content through the range where this tends to cause screen blinding; it is high with worn roll shells and with light spring pressures, low with light loads.

Extensive work at CONSOLIDATED M. & S. Co. (*61 CMJ 497*), directed toward increase in capacity, showed that higher capacity, smoother operation, and a finer product were obtainable in closed than in open circuit.

Tonnage in a circulating load may be estimated from preliminary crushing experiments in which oversize from original crushing (in the type of machine to be used and at the setting to be employed) is recrushed, and its oversize similarly recrushed, with intervening sampling and sizing on a test screen of the aperture of the closing screen. Such a test, involving not more than two or three recrushings, should reach a constant ratio of return b. If crushing is to be free, it is unnecessary to feed back returns with more new feed, but if choke-crushing is to be employed, the feed rate to the rolls must be kept up to choke conditions with an estimated proportion of new feed present, and the determination of b will involve considerable ingenuity and guesswork. With b established, total tonnage in the circuit (T_T) may be calculated from the tonnage of original oversize (T) by Eq. 16.

$$T_T = T/1 - b \tag{16}$$

and circulating tonnage (T_c) = $T_T - T$.

Size of product. The lower limit of size for efficient roll crushing is not clearly established, but certainly it is not below 10-m. Where a product passing a 10-m. screen is all that is desired, it is usual and probably more economical to complete the crushing in rolls than to install rod or ball mills, but at RAY and at TENNESSEE COPPER CO. large fast-running rod mills have proved cheaper than rolls for comminution through the range from 1-in. to 10-m. limiting size, the saving being primarily in the steel consumed, and amounting to 2 to 3¢ per ton. Following these showings, several rod-mill installations have been made in plants producing sand for concrete. When the product wanted is finer than 10-m., and no metallurgical considerations enter, ball or rod mills are invariably used for final comminution, and the question then arises as to how far crushing should be carried, since rod and ball mills can operate on 3-in. feeds. The weight of present (1943) practice is to send feed to the ball mills at limiting sizes between $^1/_2$-in. and $^3/_4$-in., in which case rolls are not used; the copper mills are the striking exception to this practice, since they crush to 10-m. for ball-mill feed, and, with few exceptions, do so in rolls. The gravity-concentration mills likewise use rolls down to 10-m., and occasionally somewhat finer, but 20-m. crushing in rolls is much more expensive than ball milling.

Graded crushing is an operation of gradual reduction in size by means of a series of crushers, each set with a smaller discharge aperture than the preceding, while material fine enough to pass the following crusher is removed between the crushing steps. The purpose is to minimize production of slimes. Size reduction in successive steps in graded crushing is usually small; working reduction ratios are of the order of 1.5 or 2.5. The alternative extreme is to break down with as big steps in reduction ratio as the size and strength of the crushing machines will permit, with no removal of fines ahead of successive crushers, except that the last crusher in series is in closed circuit with a limiting screen.

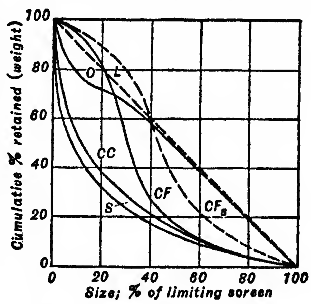
During the years before the introduction of flotation processes in base-metal milling, when minimum sliming was essential to maximum recovery, the tradition that graded crushing was necessary was established, apparently with very little experimental evidence. An exhaustive investigation by the NEW JERSEY ZINC Co., crushing a sphalerite ore with granitic gangue from 1-in. to 0.1-in. maximum size in rolls, showed that the amount of <0.025-in. material produced was the same, within a range of about 2% of the weight crushed, irrespective of the number of steps or the presence or absence of intermediate screening. Small-scale intermittent tests at COLUMBIA UNIVERSITY gave similar results. Further tests in the Columbia laboratory have shown that the sizing test of the product of a pair of rolls with a given set is substantially the same with a given rock, irrespective of the size of feed, provided only that the rolls are free-crushing, that they will nip the particles, and that there is no undersize present in the feed. The significance of the last restriction lies in the fact that if the various feeds contain different amounts of undersize these will have different effects on the screen tests of the products, even though they pass through without any breaking. These facts would seem to establish definitely that there is no advantage from graded crushing and intermediate screening in free-crushing in rolls.

Corrugated rolls differ from the plane rolls already described in that the shells are corrugated transversely. Corrugated shells are used in a few metal mills, usually where the feed is too large to be nipped by rolls with plane shells.

At HOLLINGER (*Bul 117 CMI 343*) a set of 40×20-in. transversely corrugated rolls set at 0.75-in., running at 110 r.p.m. and drawing 45 hp., took the product from three gyratories, one set at 1.5-in. and the others at 2.5-in., at the rate of 125 t.p.h. Finger gears were used on these rolls to keep the corrugations in mesh. The driving motor had a double-throw switch to allow reversal in case of clogging. The shells were manganese steel, 4 in. thick. One set weighed 4,730 lb. and crushed 200,000 tons, so that steel consumption was 0.024 lb. per ton crushed.

Character of roll product varies according to the character of feed, the type and setting of the rolls, whether crushing is free or choke, and whether operating in closed- or open-circuit. Fig. 49 gives characteristic sizing curves of smooth-faced spring-roll products from average rock.

Curve *O*, for free-crushing in open circuit is, barring the small dip in the fine sizes, substantially a straight line, and justifies the common assumption of a straight-line relationship between cumulative weight retained and size in the product of such crushing of sized feeds. Curve *CF* is characteristic of free-crushing in closed circuit. Circulating load is usually light. When this curve is corrected for a small amount, usually less than 5%, of material retained on the coarsest screen (see curve CF_s), the average is very close to the direct-proportion straight line; the dip at the coarse end being caused by the repassage, substantially uncrushed, of the finer part of the circulating load, and the hump at the fine end being due to the effect on percentages of this uncrushed circulated material, from which the proper proportion of fines is not made. The curve would seem to justify closed-circuiting in free-crushing when the desideratum is the production of a maximum of granular product with a minimum of slime. Curve *CC* is characteristic of choke-crushing in closed circuit with heavy (>300%) circulating loads; the concavity of the curve is a reflection of both interparticle grinding (fine end) and inability of the machine to hold back flats (coarse end). Curve *S*, characteristic of the closing-screen undersize in a circuit with rolls producing material of the character *CC*, is simply a reflection of *CC* with the coarse end removed and the concavity-producing effect of the fines intensified. It is apparent that when the limiting screen is of small aperture, *e.g.*, 10-m., a considerable burden is taken from the subsequent grinding mill; it is further apparent that this is not the way to crush when minimum slime production is the aim.



O = Open circuit, free-crushing.
CF = Closed circuit, free-crushing.
CF_s = Curve *CF* shifted (see text, this page).
CC = Closed circuit, choke-crushing.
S = Closing-screen undersize, closed circuit choke-crushing.
L = Ideal product curve.

FIG. 49. Characteristic sizing curves of roll products.

In the open-circuit work recorded in Table 24, while the data are meager, it is indicated that with rigid rolls, or spring rolls run at high pressures, doing coarse crushing and not heavily loaded, the limiting size of nonslabby material is about twice the set, as is to be expected from the shape factor; the percentage coarser than the setting is 20 and that finer than half the setting is 60. With coarse feed, relatively coarse settings, average loading, and the comparatively light spring tensions normally used in free-crushing work, the limiting size is about 4 times the setting, ranging from 2.5 with a 1-in. set to 5.3 with a 3/16-in. set; percentage coarser than the set is 45 and that finer than half-set is 25. This may be taken as the average condition. (When tramp oversize is eliminated from this material its sizing curve approximates *O*, Fig. 49). One machine set at 1/16-in. and taking >1/2-in. feed at an average rate had some >3/8-in. material in the product, showing a limiting size 8 times the set, 80% coarser than the setting and only 15% finer than half-set. This indicates either very low spring tension or badly corrugated shells.

In closed-circuit operation, free-crushing, the product of the rolls (not the closing-screen undersize) is not greatly different in character from that of open-circuit work except that the ratio of limiting size to set is a little higher and the proportion coarser than set is, perhaps, slightly greater. When choke-crushing, with high circulating loads (>200%) and feeds coarser than 1/4-in., the average ratio of limiting size to set is 3 or 4, the percentage coarser than set is 20 to 40, averaging close to 30, and the percentage finer than half-set ranges from 30 to 60, averaging between 40 and 50. (It should be noted that the set in such crushing is not the nominal set but approximately 0.3 times the limiting size of product (see p. 72); if nominal settings are used in the analysis, the percentages quoted are almost random scattered.)

The undersize of the closing screen in heavy-duty closed-circuit choke-crushing, where the closing screen is smaller than true set, has a limiting size: set ratio normally less than 1.0; the percentage coarser than set is, therefore, zero; and the percentage finer than half-set is substantially 80.

Making a closely sized product. In many industrial-mineral plants (*e.g.*, chip roofing, chick grits, abrasive, etc.) the desideratum is to produce a maximum percentage of some particular granular size. Owens (*42 IMM 407*) points out that while the quantity of fines produced by free-crushing in rolls will increase steadily from zero at a roll set larger than the largest feed particle, and approach 100% at zero set, and the quantity of particles near the coarsest present in the feed will, conversely, increase from zero at zero set to 100% at a set larger than the largest feed particle, the amount of any other size produced will pass through zero at both of these limiting settings and will, consequently, pass through a maximum at some intermediate setting. By running a series of tests, therefore, at a number of settings, varying capacity correspondingly to maintain the maximum, and plotting quantities of the desired granular product against the set, the set required for maximum production of the desired size may be determined.

Operation. The essence of successful roll operation is frequent inspection and immediate attention. Shafts should be kept in alignment and springs kept up to tension; set should be maintained, and unequal wear of shell faces and flanging of the edges should be prevented or minimized; all bolts should be kept tight and shims maintained in place to prevent slapping together of roll faces. Failure to attend to these things will invariably increase lost time and maintenance charges. Bearings should be rebabbitted immediately, if uneven wear destroys alignment. Springs should be kept at such a tension that there is no visible compression when only rock is going through; tension in the two cages must be equal (spacing of cage heads the same) to prevent lack of alignment; tension on all individual springs in a cage should be the same (distance between heads at four corners equal); and in setting, the spring-cage tension must be taken up on the main tension rods, or the cage bolts will be broken. Chatter and vibration usually indicate low spring pressures. Cores should be set up as tightly as possible when new shells are set; core bolts should be tested (and tightened) within 24 hr. after a new shell is put into service, and should be inspected at two-week intervals at the most thereafter. Frequent lateral shifting will prevent edge flanging and minimize corrugation, and, coupled with changes in the feed stream, will go far toward preventing the latter. Loose foundation bolts induce vibration and any such movement in such heavy machines is highly destructive. Failure to maintain set increases circulating load with corresponding increase in wear and transport charges; and if any unit in the flow is normally working to capacity, new-feed tonnage must be reduced correspondingly.

Cost of roll crushing. The elements of cost are power, labor, repairs, and lubrication. One man can attend 3 to 12 sets of rolls; the average in 20 plants investigated, where the roll tender had no other duties, was 6. Repairs may be estimated at about twice the cost of roll shells. Consumption of lubricant ranges from about 2 to 50 lb. per 24 hr. On the basis of these quantities the cost of crushing to $<1/4$-in. should not exceed \$0.07 per ton in small rolls (36-in. or less diameter) nor \$0.045 in large. Addition of charges for screening and conveying in closed circuit will bring the total up to about twice these figures for best conditions. Coarse crushing will cost considerably less on account of smaller power consumption and labor cost.

Applicability. The competitors of rolls for crushing hard rocks are: the reduction crushers of the gyratory type, at the coarse end; and tumbling mills at the fine end. The hammer mill competes over the entire range for nonabrasive rock. For feeds down to 1-in. and products down to $1/2$-in., limiting, the great majority of users have resolved the competition in favor of the reduction crushers; for products finer than 10-m., limiting, the competition is similarly lost to the tumbling mills; but for the reduction from 1-in. limiting feed to 10-m. limiting product there is no consensus of practice or opinion. The weight of the evidence at present (1943) would seem to be, however, that the short-head cone in closed circuit is generally cheaper with closing screens down to $3/8$- or $5/16$-in. but not finer, provided the ore is not clayey or otherwise sticky. There is considerable evidence that rod mills will take $<3/4$-in. to <1-in. abrasive feed and make <10-m. product more cheaply than rolls, when no closing screen is used with the rod mill and screens are used to close the roll circuit. The advantage of the rod mill is primarily in the simpler circuit, absence of accessory screening and conveying equipment, and lower-priced steel; the price per pound for high-carbon steel rods was (1939) about 3.5 to 4¢ compared with 12 to 30¢ for roll shells. Comparative consumptions are about 0.4 lb. per ton of rods *vs.* 0.03 lb. per ton for high-priced shells and 0.09 lb. for the low-priced shells. Many more mills, however, are using rolls over this range than are using rod mills. More mills crush through the range from $1/2$-in. to 10-m. in ball mills than use rolls to make 10-m. ball-mill feed, but in the low-cost large-tonnage mills the latter practice predominates. On the other hand, in small mills the elimination of one crushing stage and the concomitant installation of a ball mill of larger diameter than would otherwise be justified is almost universal, and the greater efficiency of the large mill would seem to more than counterbalance the lost efficiency involved in crushing the large feed particles therein.

Selection of rolls. The necessary data for setting up the problem are: sizing test of feed, limiting size of product, size distribution desired in product, hourly tonnage, and character of rock. The method of solution is indicated in the following examples.

Example 1. To select a set of rolls to crush 50 t.p.h. of granite from <1-in. standard-cone product to $<1/4$-in. with minimum production of fines. The specification of minimum fines makes free-crushing necessary (Fig. 49). Specification of $R_L = 4$ imposes the necessity for closed circuit, if the reduction is to be done in one stage. Set must be $0.25/1.7 = 0.15$-in. to produce $<1/4$-in. square-mesh granite, taking shape factor $= 1.7$. Minimum diameter of rolls $= 40[(1/1.7) - 0.15] = 18$ in. (for 25° nip angle). Standard cone product contains 40% $<1/4$-in., hence net tonnage of new feed $= (0.6 \times 50)/0.85 = 35.3$ t.p.h. Circulating load must be relatively high to make $R_L = 4$, say 200%, hence total hourly tonnage is $35.3 + 70.6 = 105.9$. Ribbon tonnage $= (100 \times 105.9)/55 = 192$, taking a low ribbon factor to insure free crushing. Place this value for C in Eq. 14, and letting $w = 24$, $\delta = 2.6$,

and $N = 100$, for a trial solution, $D = 60$ in. Hence 60×24-in. rolls at 100 r.p.m. are indicated. A check on this estimate is obtained by comparing the reduction capacity required against average reduction performances of such rolls. From Fig. 42, w_{80F} in the present case is 0.62(1.0) = 0.62-in. From Fig. 49, $w_{80P} = 0.62(0.25) = 0.16$-in. $R_{80} = 4$. $T_R = 4(35.3) = 141.2$. Average T_R for 60-in. rolls from Table 24 is 150. Nip angle will be 14°. Moderately heavy duty rolls will serve, since the operation is free-crushing.

Example 2. To select a set of rolls to crush 50 t.p.h. of granite from <1-in. standard-cone product to <10-m. ball-mill feed. Maximum fines production is desirable; hence choke-crushing with a heavy circulating load is necessary. Table 24, item 33, shows that the reduction can be made in one step, using a 10-m. screen to close the circuit. Set may be close or a small open set; the mean set may be approximated on the score that R_L based on roll feed and unscreened roll product in choke-crushing ranges from 1.4 to 3 (Table 24), being larger the heavier the loading; taking a value of, say, 2.5, the limiting size of product would be 0.40-in., the corresponding thickness = 0.40/1.7 = 0.24, and the mean set one-half of this = 0.12-in. Net tonnage of new feed, from Fig. 42, is approximately 0.9(50)/0.85 = 53 t.p.h. Circulating load must be high to effect heavy choke-feeding, say 450%. Total tonnage = 5.5(53) = 290. Ribbon factor for heavy choke-feeding and small set may be taken as 250, hence theoretical tonnage = (100 × 290)/250 = 116. Substituting this value in Eq. 14, using $w = 24$, $\delta = 2.6$, and $N = 100$ for a trial solution, gives $D = 45$ in. To check this against performances: $w_{80F} = 0.62$ (Fig. 42); $w_{80P} = 0.024$ (Fig. 49); $R_{80} = 26$, and $T_R = 1{,}380$. Performance values of T_R for 45-in. rolls range from 250 to 300 with $R_{80} = 5$ and increase proportionately to increase in R_{80}; taking the 300 and making the adjustment, 26(300)/5 = 1,560. The assumed peripheral speed, (100 × 45 × 3.14)/12 = 1,180 f.p.m., is well within the limits for heavy-duty rolls, hence by speeding up a roll of narrower face somewhat, 43- or 44-in. diameter may be used, but modern practice would tend toward larger diameter and somewhat slower speed for the sake of operating economy and to give reserve capacity.

9. HAMMER MILLS

Use. The HAMMER MILL, or SWING-HAMMER CRUSHER, or PULVERATOR, or IMPACTOR, as it is variously known, is used either as a one-step primary crusher for reducing run-of-quarry material to as small as <1-in. size, or as a secondary crusher taking 4~8-in. primary-crusher product down to <3/4-in. or finer. Its use as a rock crusher is almost wholly confined to the softer, easily crushable materials such as phosphates, gypsum, barite, asbestos rock, cement rock, and the like, medium-hard limestone being the hardest rock commonly crushed; as a secondary it is used for more abrasive material, especially if this is brittle, and scattered instances are reported of its use on siliceous gravels; in general, however, high maintenance is to be expected, if the siliceous content of a feed is in excess of 5%. The mill is particularly useful for clayey material that would clog reciprocating-type primary crushers. It also has wide use in crushing bituminous coal at coke-oven and power plants, and in disintegration, by shredding, of various fibrous organic materials such as plant stems (wood and straws), bones, and hoofs.

Description. The machine, of which a number of different forms are shown in Fig. 50, comprises essentially a plurality of flailing hammers *a* which strike rock particles either when they are falling freely through air or as they rest on a stationary metal surface *g* inclined more or less in the direction of the hammer travel, and the struck particles, or fragments thereof, are thereupon thrown with great force against other fixed surfaces *k* surrounding the flailing hammers, or are pinched at an angle between the moving hammers and fixed surfaces *i*, usually perforate.

Machines of the general hammer-mill type vary widely in details of construction, particularly as regards the conformation and material of the hammers, the placing and conformation of the breaker plates, the presence or absence of and the type of exit grating, and the position of the feed inlet. A typical medium-duty grate-type machine is shown in Fig. 50, item *A*. The hammers *a* are suspended by pins *b* between heavy steel disks *c*, which are spaced along shaft *d* by suitable spacers and keyed thereto. The shaft *d* is carried in heavy bearings in the ends *e* of the main frame. A heavy flywheel is mounted on one end of the shaft; the other end is fitted with a drive pulley or is attached, through flexible coupling, directly to the driving motor. Rotation of the machine illustrated is counterclockwise. The bottom of the feed hopper *f* carries heavy breaker plates, which may be moved forward, to compensate for wear, by suitable adjusting screws. A grid or screen for determining product size is formed by the longitudinal grate bars *i*. The top of the crushing zone is enclosed by an imperforate cover *j*. As the hammers wear beyond the limits of adjustment of the breaker plate *g*, they may be rehung further from the center of rotation, in other holes (*l*). In most forms of the machine the grid frame is also hinged (see Fig. 50, items *E* and *F*) or otherwise arranged for gradual adjustment toward the center of rotation, as well as for dropping away for quick discharge of the load in case of a clog-up or sudden shutdown.

Feed entry is variously arranged. In some machines (Type I) entering coarse material is first struck while partly supported against a stationary plate (Fig. 50, items *A*, *E*, *G*) and the hammers tend to drive broken fragments toward the grid; in others (Type II) entering material is first struck by rising hammers (Fig. 50, items *B*, *D*, *F*) and fragments are thrown against breaking plates along the top and downcoming sides, from which they bounce back into the hammer path for further blows before they

reach the grid; and in yet others (Type III) the first blow is substantially horizontal (Fig. 50, items *C*, *H*, *I*, and, to a certain extent, in *G*), with some opportunity for reflection into the coarse-crushing zone before falling into the fine-crushing zone on the grid. The form *I* has heavy anvil bars carried on adjustable plates, so that the bars may be spaced at the most favorable distance from the hammers. On the grid the crushing action is, in part, simple impact against unbacked-up particles, and in part shear of pieces wedged between or lying upon the bars. Type I machines are medium- to light-duty; Types II and III heavy-duty.

Grid is sometimes omitted (Fig. 50, item *I*), particularly in top-feed machines, in order to save excessive wear with abrasive feeds, or to escape clogging with sticky materials. The rotor is usually

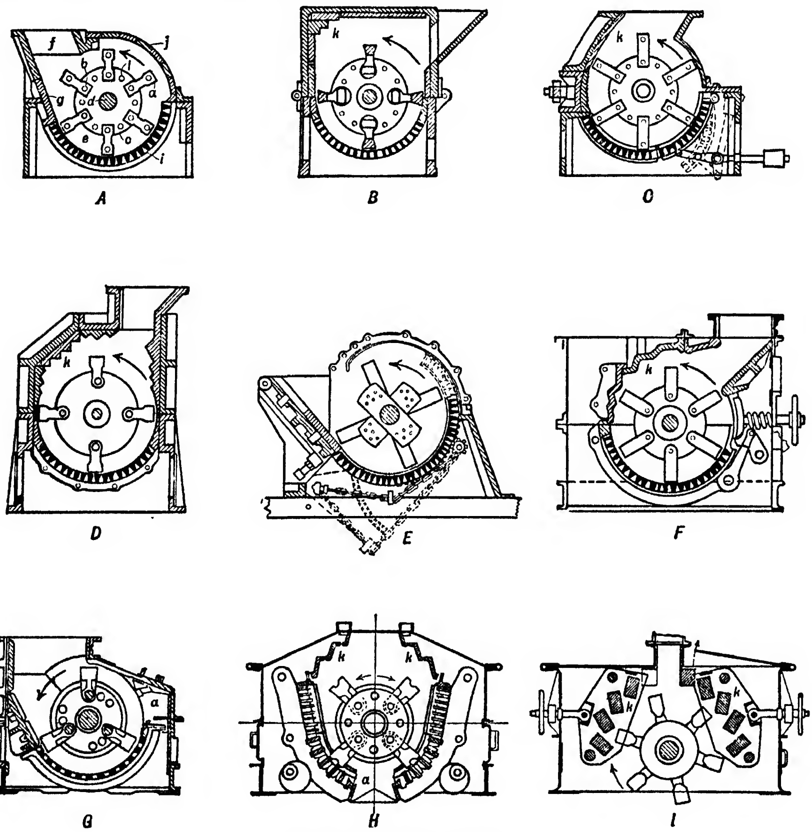


FIG. 50. Hammer mills.

speeded up for such service, but, even so, there is no positive guard against discharge of oversize, and if a definite limiting upper size is important, the machine must be put in closed circuit with a screen. In secondary crushing and in pulverizing service a separate circuit-closing screen should always be used whether the machine contains a grate or not. (See also *Grates*, p. 81.)

Tramp iron in feed is a source of grate-bar and hammer breakage, with possible resultant wreckage of the entire machine. Where possible, it is best removed by a magnet on the feed line. Some forms (Fig. 50, items *G* and *H*) provide a catch pocket *a* into which it is hoped the iron will be somewhat preferentially flung by centrifugal force and held for cleanout.

Main frame in large heavy-duty primary machines is made of deeply ribbed cast-steel sections with the main bearings and the bearings for the swing shaft for breaker plates and grid frame cast integral in a one-piece base. The upper housing is either cast or built up of plate and structural shapes. In either case flanged joints, carefully machined, are provided for bolting the housing to the frame. The hopper is made of rolled steel shapes and plates. In machines for lighter duty only the ends of the base are heavy iron or steel castings, with cast seats for the main bearings; rolled structural shapes and heavy plate are used for the balance of the frame and housing.

Housing should be kept down in size as much as is consistent with sufficient spacing of anvils or breaker plates. These latter are necessarily tough as well as hard; they consequently flow when worn unless properly backed. If the necessary backing is made an integral part of them, the discard is rela-

tively enormous; hence either they must be backed against the housing, or a special backing frame must be provided inside the housing.

The housing should provide ready access for changing hammers; this is especially important with abrasive material, where hammers may require reversal as often as once per 24 hr.

Shaft is made very heavy, of forged high-carbon or alloy steel. In one machine the shaft is 22-in. diameter through the crushing zone and turned down to somewhat smaller diameter at the bearings.

Bearings are of extra heavy ring-oiling dynamo type or, in the best machines, of roller type. Every endeavor should be made to dustproof them efficiently.

Disks (*c*, Fig. 50, item *A*) are made of cast steel, with heavy hubs, bored and keyseated for the main shaft, and carefully bored in register with each other for the hammer-spending pins. They should be made without projections from face or edge essential to their functioning, as these wear excessively and thus shorten life. Designs that can be adapted to either stirrup or slugger hammers are useful.

Hammers are made of chilled iron, forged high-carbon steel, cast manganese steel, or special tough hard alloy steels, and in a variety of shapes according to service (see Fig. 51). They weigh from a few pounds to 250 lb. each.

Forms *A*, *B*, and *C* are BAR TYPE for light duty; *A* and *C* for relatively coarse product, *B* for a finer product produced by more attrition grinding on the grid. Forms *D*, *E*, and *F* are of the so-called SLUGGER TYPE, for heavy duty; in each of these forms some provision is made for saving discard metal.

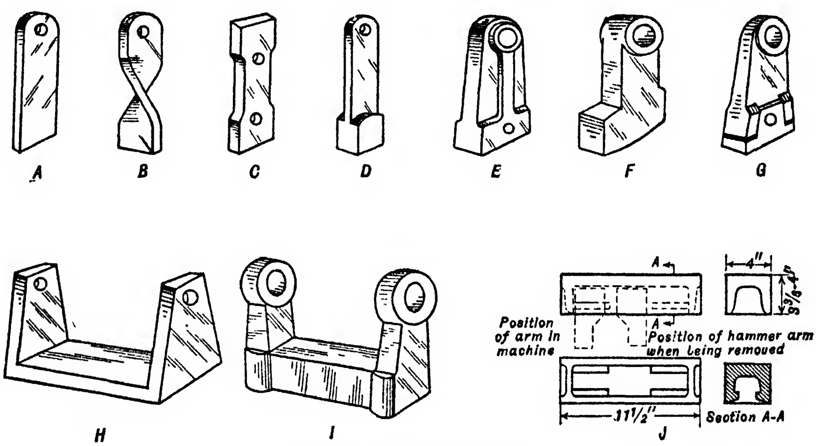

Fig. 51. Types of hammers.

Such forms are usually heat-treated to produce hard heads and tough shanks. Form *E* is cast with a cored-out head to permit compensation for wear by means of additions of lead in the cored cavity, with the idea of thereby decreasing troublesome and possibly destructive vibration due to uneven wear. In some forms, *e.g.*, form *F*, the hole for the rotor pin is cored out for bushings of various eccentricities to permit maintenance of a relatively constant hammer circle, as a remedy to vibration. Form *G* has a replaceable head, designed to be pinned to the shank; this is better than similar forms with riveted heads, but the pins bend in service and are hard to remove; heads held on by lugs are better, if they are so designed as to insure against loss while running. At NORRIS DAM (*129 A 185*) the use of pinned heads on stirrup hammers added 8¢ per head for labor in changing, and the shutdown time was appreciably longer. Forms *H* and *I* are light and heavy STIRRUP TYPES respectively; they strike with greater impact than the slugger types, and are more effective in attrition grinding on the grid, but when they are forced back, more of the effective hammer circle is lost, and with them the rotor gets out of balance more frequently owing to uneven wear. At NORRIS DAM, in secondary service, they made more finished product per hp-hr. and per lb. of hammer than the slugger type. Form *J* is a stirrup hammer with replaceable head, lug type, used at NORRIS DAM. A later form, designed with deeper sides, a bridge at the center, and with the face troughed, gave definitely longer life and lower metal costs per ton; the deeper sides increased the area of striking surface, which reduced both circulating load and wear on hammer arms; the bridge prevented deformation and thus made removal of worn heads a simpler and quicker job. The average new weight of heads was 28.6 lb. and the discard weight, 18 lb. If sides are made too deep for complete penetration (see p. 81), rejection weight increases owing to lack of wear at the inner portion. The trough reduced discard weight without reducing life. This change in design reduced metal cost for manganese-steel hammers from 1.69 to 1.28¢ per ton, and for chrome-steel from 2.46 to 1.78¢. The essence of hammer design is to so apportion the metal that the head will maintain a face as large and as nearly in a radial plane as possible until wear has reached the point that breakage is imminent. With renewable tips, one shank will usually last as long as 3 or 4 tips.

Capacity of open circuits is decreased, and circulating loads in closed circuits tend to increase rapidly after the hammers are about half-worn, but the net reduction per hp-hr. is not greatly affected by hammer wear except near the end, provided penetration is complete. At WISCONSIN STEEL Co., in

crushing bituminous coal with partly worn hammers, capacity was 206 t.p.h. and power draft 345 hp.; 2 months later, after change to new hammers, capacity was 234 t.p.h. and power consumption dropped to 319 hp. At another plant the power consumptions with new and old hammers (140,000 tons for Lucas slugger-type and 1,000 tons per tip for Hiller bar-type) respectively were: Pocahontas, 0.8 and 1.0 hp-hr. per ton; Elkhorn, dry, 1.65 and 2.15; wet, 2.2 and 2.7; Roda (medium hard), 1.3 and 1.8.

Other special-shaped hammers are used for special industrial services.

Reversibility. All forms of hammers are reversible to compensate for rounding with wear. Some machines (Fig. 50, *H*) are built for reversible rotation to equalize wear on hammers and grid bars, and eliminate necessity for reversal thereof. With abrasive material this is important. At NORRIS DAM, with a limestone carrying 3 to 8% uncombined SiO_2, mills had to be stopped for hammer reversal every 17 to 27 hr. and for hammer change half as frequently. Time for hammer reversal is about 45 min.

Rows. Hammers are arranged in 2, 3, 4, and, rarely, 6 rows, the smaller number being used for coarse feed and discharge when the desiderata are heavy blows, quick discharge, and correspondingly high capacity; the greater number for fine pulverization, where the greatest possible number of relatively light blows is desired.

Extensive tests at NORRIS DAM (*129 A 185*) showed that for crushing <3-in. cherty limestone through 1/4-in. 3 rows made more finished product per hp-hr. than either 6 or 2, although as between 3 and 2 the difference was small. Three rows produced more circulating load, with consequent greater metal consumption in the mill and higher screen wear. The essential factor here is penetration of particles into the hammer "cylinder"; if this is too little, owing to lack of time interval between successive hammer rows, the forward outer edge of the hammer rounds off quickly and thereafter material is struck glancing blows, circulating load increases, and new feed must be reduced to prevent clogging. On the other hand, breakage of brittle hammers tends to be less with a greater number of rows.

Table 25. Relative wear of hammers at Norris Dam

Metal	Order *a*	Relative wear *b*	Price, cents per pound delivered
Cr-Mo steel	1	0.64	22.5
High-carbon steel	2	0.74	24.0
Cr steel	3	0.75	21.5
Mn steel, hard-surfaced with Amsco 459 weld rod	4	0.79	38.7
Mn steel, hard-surfaced with Amsco 217 weld rod	5	0.80	37.5
Mn steel, hard-surfaced with Borod weld rod	6	0.80	39.0
Mn steel hard-surfaced with Stellite weld rod	7	0.84	37.0
Mn steel, cold-worked all sides	8	0.89	23.9
Mn steel, hard-surfaced with Studite weld rod	9	0.90	30.0
Mn steel, hard-surfaced with Hascrome weld rod	10	0.92	36.8
Tempered high-carbon steel	11	1.00	22.5
Mn steel, cold-worked two sides	12	1.01	24.2

a Wear resistance decreases as order number increases.
b Compared to No. 12.

Material of hammers has a marked effect on economy of operation if abrasion is high, since hammers cost 10 to 15¢ upward per lb. and the mill must be down 5 to 10% of a 24-hr. operating schedule for hammer changes. Hammer breakage is disastrous for the reason that a broken hammer loose in the mill will usually break others before the mill can be stopped, with resulting havoc not only to grates but also to rotor disks and shaft, bearing caps, and to motors, if these are direct-connected. Table 25 gives relative wear ratings on cherty limestone at NORRIS DAM. The chrome-alloy hammers were highly uneven in quality, some brittle to the point of early breakage, some so soft that wear was double the normal. From the standpoint of operating cost, with labor cost for hammer replacement 0.2¢ per ton of finished product, the No. 12 hammer of the stirrup type was cheapest on this particular operation, with an overall hammer cost of 1.33 to 1.68¢ per ton of product. Comparative costs for bituminous coal are 0.15 to 0.35¢ per ton.

Breaker plates are variously located, shaped, and arranged according to the designer's ideas of the service and to the location of the feed hopper. With underfeed machines, *i.e.*, those fed under the downcoming hammers (see Fig. 50), and with a relatively coarse discharge grid, the breaker plates form the bottom of the feed hopper, they are usually made with plane surfaces, they terminate and the grid starts at or near the 45° line through the shaft center. They are inclined at about 45° to the horizontal (a ready sliding angle) when the feed is dry and nonsticky; for wet or sticky feed the inclination is increased to 75° or more. For fine crushing with underfed machines the breaker plate is extended downward to a terminal point directly below the shaft and corrugated parallel to the shaft, whereas the grid is extended upward correspondingly to enclose about 180° of the periphery. In overfeed machines the breaker plates are placed along the top of the housing and are usually made with coarsely stepped surfaces so arranged as to present flat surfaces at right angles to particles flung off tangentially by the hammer blows. In center-feed types the breaker plate occupies the upper part of the housing on the downcoming side and is ridged or corrugated. At NORRIS DAM corrugated breaker-plate surfaces produced a finer product than those with smooth surfaces.

Breaker plates should be heavy so as to make renewal infrequent, and of such shape that the amount of waste is kept at a minimum. The latter desideratum points to small sections, but joints concentrate wear; consequently sectionalizing that involves jointing is usually confined to places such as the feed lip in underfeed machines where wear is excessive and where failure to sectionalize would result in a very high discard ratio. Plates should be backed against the casing, if possible; otherwise they must be backed in some other fashion to prevent flow when worn thin. They should be designed for reversibility; they should be fastened by bolts that do not go through to the wearing face, since wear concentrates around bolt heads thus placed. Stepped plates should be so arranged that successively lower steps successively approach the hammer circle. For secondary work the lowest bar should be adjustable to compensate for wear. Relatively close clearances here in fine work take much wear off the grates. Some sort of stop is advisable, if adjustment is to be made with the mill running, to prevent pushing the plate into the hammer circle. Usual MATERIALS are chilled iron or alloy steels, cast manganese steel being the most usual. At NORRIS DAM, cost of manganese steel plates was 0.75¢ per ton of product, or about half the hammer cost.

Grates or CAGES occupy from 135° to 180° or more of the periphery of the shell surrounding the rotating hammers, usually the bottom portion, but in some fine-crushing machines they are moved around toward the upcoming side of the circle. Various forms of grate and supports are shown in Fig. 52. Perforated-plate cages are also used. The bars are usually made wedge shaped and set with broad ends inward so as to offer a flaring discharge path and thus lessen clogging, but in some mills they are rectangular in section and consequently reversible. They must be strong enough to resist the stresses set up when pieces wedged between them and projecting inward to the hammer circle are struck. Intermediate support is usually provided by the frame in which they are carried. Cross-section depends on service and is only to be determined by experience, since the stresses cannot be approximated. Metal loss per ton crushed will be less, however, if they are so designed as to minimize change in discharge aperture with wear, *i.e.*, if the metal provided for strength is put into depth rather than width. This presents an overturn problem, however, as well as a lack of transverse strength to resist the stresses set up by sweeping blows against wedged material. Excessive thickness is inadvisable because loss in capacity and increase in power consumption owing to lost sharpness on the leading edge becomes serious long before breakage is imminent. The grate frame, in secondary machines particularly, should be so mounted as to permit adjustment toward the hammer circle to compensate for wear. Close setting promotes attrition breaking but, of course, increases wear (see Fig. 57). Bars are made of chilled iron or alloy steel. At NORRIS DAM tool-steel bars cost 4 times as much as cast-manganese-steel grates, with tapered bars 1 in. wide at the top (1.82¢ per ton of product *vs.* 0.51¢). Reversible bars 1 1/2×5-in. section with 6 spacing lugs in 4-ft. length were also used. Blank plate requires more power than perforated plate.

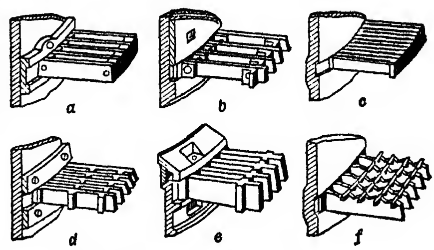

FIG. 52. Hammer-mill grates (*124 J 930*).

Grate bar spacing determines thickness of the largest product particles, but the size of product is normally much finer than would be expected from the grate acting as a simple screen. In secondary and fine service the closing guard is usually and properly a separate screen, in which case grate spacing is ordinarily 6 to 8 times the screen aperture; the smaller the spacing, of course, the less the circulating load, but ultimate capacity is not greatly affected unless the spacing is too small.

Grate frame is usually arranged to permit varying the spacing according to the fineness of product desired.

Feeding. Feed must penetrate the hammer circle, if the full area of the crushing surfaces of the hammers is to be utilized. This necessitates a balance between falling velocities and rotor velocities that will differ with the position and direction of feed entry with respect to the rotor, and with the depth of the crushing face of the hammer. If feed-particle velocity is too great, the rotor disks and hammer shanks wear excessively; if penetration is insufficient, hammer heads round off at the outer ends, material is struck glancing blows with consequent lack of force and imposed velocity, capacity falls off, circulating loads build up, and the machine cannot be made to draw full power without quick overloads and clogging. In center-feed machines the feed-box height is made adjustable to permit control of penetration, and adjustment with hammer-head wear.

Manufacturers. Allis-Chalmers Mfg. Co., American Pulverizer Co., Dixie Mach. Mfg. Co., Gibson, W. W., Gruendler Crusher & Pulverizer Co., Jeffrey Mfg. Co., Pennsylvania Crusher Co., Sturtevant Mill Co., Williams Patent Crusher & Pulverizer Co.

Manufacturers' data, composited from a number of catalogues, are given in Tables 26 and 27.

Forces in hammer-mill breaking are not known with any great degree of accuracy. The general method of analysis is, however, well established, and some of the variables can be approximated for any given operation.

If, in Fig. 53, H represents a section of a steel hammer moving in the direction indicated by the arrow, with velocity u, and b is a steel ball of weight w, which, at the instant of impact was falling vertically

(with no component of velocity in the direction of the hammer movement), then b will be deformed somewhat as is shown and, if the mass of H is sufficiently great that it does not lose any appreciable velocity due to the impact, b will thereafter attain a velocity v in the direction of u of a magnitude approximately equal to $1.8u$. If M is the momentum of b in the direction of u as b is thrown from H, then $M - 0 = M$ is the change in momentum, and the average force F_{av} of the blow is M/t, where t is the time interval required for b to attain the velocity v. Hence, for the condition postulated, $F_{av} = 1.8wu/gt$. The maximum force, F_{max} = approximately $1.5F_{av}$.

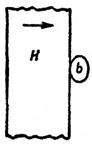

FIG. 53. Elastic sphere against hammer face at instant of impact.

The value of t for highly elastic impact is about 0.001 sec. For inelastic impact, such as with a lead ball, $v = u$ and t = about 0.002 sec. Values of v and t for rock probably lie between those for steel and lead.

The same formula applies to the case when a piece of rock is thrown against a breaker plate. Taking values for rock as for lead, and English units, $F_{max} = 1.5wu/32.2(0.002) = 23wu$ lb. With lumps of rock sufficiently large to deflect the hammer, u decreases and t increases to an unknown extent, but probably sufficiently to cause marked drop in the effective F_{max}. Magnitudes of F_{max} from the equation are: 3 lb. for a ¼-in. cube; 21 tons for a 6-in. cube of rock of sp.gr 2.6, when u = 90 f.p.s.

Other factors that are of importance in impact crushing have been developed in the research on impact testing of metals. The internal stresses produced by a given force increase markedly with increase in the

a Crushing medium limestone to about 1 1/2-in. mesh. See ***Performance.*** For machines up to 20,000 lb. weight, the maximum feed size should not exceed 6-in. for limestone, or 9-in. for gypsum, burnt lime, shale, or the like; bituminous coal may be any size that the machine will receive. Machines from 20,000 to 40,000 lb. weight will take 12- to 14-in. limestone, and 18- to 20-in. gypsum, etc. The heavier machines will take medium-hard limestone as large as will enter the receiving opening, but in general it will be wiser to choose one of the heavier machines at a given size of receiving opening, if run-of-quarry rock is to be fed.

b See Figs. 58, 60.

c See ***Power consumption***, p. 86.

velocity of force application, so that forces of a given magnitude applied by a hammer mill are much more effective in breaking than forces of the same magnitude applied gradually. The rise in local stress in impact loading is much greater than in static loading; this is important in that loading of rock fragments occurs on relatively small local areas. The yield point increases with increase in rate of loading whereas the ultimate strength does not, so that, with sufficiently rapid loading, yield point may pass ultimate strength and brittleness be thus engendered. In other words, a rock that tended to be plastic in jaw-crusher breaking might be brittle in a hammer mill.

a Crushing medium limestone from 4- to 6-in. limiting size. See ***Performance.***
b See Figs. 58, 60.
c See ***Power consumption,*** p. 86.
d Maximum.

Performance data are scarce and lack much essential detail. Table 28, supplied by PENNSYLVANIA CRUSHER Co., was made up from eight operating records on mills breaking cement rock.

At Howes Cave plant of NORTH AMERICAN CEMENT Co. (*IC 6553*) a machine with 48-in. hammer circle at 900 r.p.m. crushed <9-in. limestone through a 2-in. grid at the rate of 117 t.p.h.; >1/4-in. from this product was further reduced through a 1/4-in. grate in a second machine with 100-hp. motor at the rate of 38 t.p.h. At the Security plant of the same company (*IC 6554*) an SXT-14 Pennsylvania machine at 720 r.p.m. crushed <9-in. limestone to <1/4-in. at the rate of 128 t.p.h., and a secondary machine with 42-in. hammer circle at 900 r.p.m. crushed the product through a 1/2-in. grid at 75 t.p.h. At UNIVERSAL ATLAS CEMENT Co., Hudson plant (*42 #2 RP 31;* see also Sec. 3A, Fig. 18) a 58-in. 16-disk hammer mill with 700-hp. motor takes <9-in. product at the rate of 250 to 310 t.p.h. and reduces it to 96% <1-in. in one pass. Feed drop of 5 ft. is sufficient for penetration. Motor is reversed every third day. Consumption of manganese steel is about 8 lb. per 1,000 tons of feed. Power consumption is 1.6 hp-hr. per ton. At NORRIS DAM (*PC*), a 42(diam.)×48-in. machine, with grates spaced 2 in., running at 900 r.p.m., crushed 150 t.p.h. of dolomite containing 6% SiO_2 from <3-in. to <3/8-in. Power consumption was 0.95 hp-hr. per ton; maintenance, 5¢ per ton. Product contained about 25% <100-m. Ferrosilicon is reported (*PC*) crushed from <2-in. to <20-m. in closed circuit at the rate of 10 t.p.h. in

a 38×30-in. machine running at 1,150 r.p.m.; power consumption 3.25 hp-hr. per ton; maintenance, 25¢ per ton. The machine has a variable-speed motor; when speed is dropped to 850 r.p.m. and closing screen is changed to 1/4-in., production rises to 15 t.p.h., power consumption is 1.50 hp-hr. per ton, and maintenance is 10¢ per ton. Aluminum oxide is crushed from <4-in. to <4-m. at the rate of 2.5 t.p.h. in a 32×11-in. machine in closed circuit with a screen; speed is 1,250 r.p.m., power consumption 5 hp-hr. per ton, and maintenance 40¢ per ton.

a Laminated, medium hardness (10,000 to 15,000 lb. per sq. in. in compression), relatively nonabrasive.

Operating variables are number and shape of hammers, with consequent differences in diameter and configuration of hammer circle; speed; number, size, arrangement, and spacing of anvil or breaker plates; height of feed chute; spacing of grate bars, both as to aperture and approach to the hammer circle; and feed rate and feed size.

Size of product depends on character of rock, size of feed, type of mill, whether or not a grid is used; whether the mill is in open or closed circuit; if the former, on the grid spacing; if the latter, additionally on the aperture of the closing screen; the shape, spacing and extent of wear of the breaking surfaces; rotor speed; clearance of hammer circle with respect to the lowest breaker plate and to the grids; hammer weight; etc. Some of these relationships for an impactor (machine without grid) are given in Figs. 54 to 59. These curves represent results (*PC*) of extensive tests on an operating machine working on tough river gravel, and, while not applicable directly as to magnitudes for softer materials, are dependable as to trends.

Fig. 54 shows that if the crushing zone is completely swept by hammers, as it was with three rows of stirrup hammers, two to a row, an increase of 50% in NUMBER OF HAMMERS produces but little additional crushing effect, and that this effect is less the higher the speed. Fig. 55 shows the loss in crushing effect due to WORN HAMMERS when speed is high enough for effective breaking (950 r.p.m.); it also shows that when speed is too low (550 r.p.m.) the state of the hammers makes little difference; in this event, in a grid machine, stalling would occur rapidly unless feed rate were greatly reduced below that at 950 r.p.m.

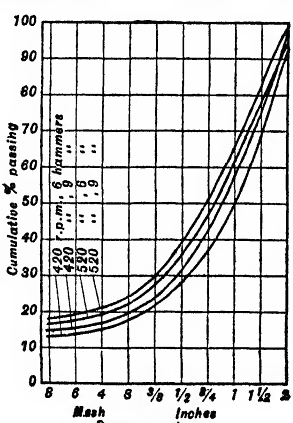

FIG. 54. Effect of number of hammers on product of an Impactor (feed, river gravel, 4 1/2~1 1/4-in.).

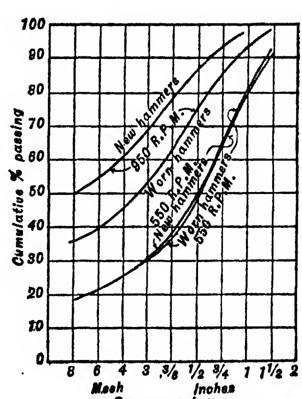

FIG. 55. Effect of hammer wear on Impactor product (feed, river gravel, 4 1/2~1 1/4-in.).

with new hammers. Fig. 56 indicates that within the usual range of ANVIL ADJUSTMENT the variation in crushing due to change in clearance is not great, but is definite, and that crushing increases with reduction in clearance. The effect is greatest in the coarse end of the product, as is to be expected. Fig. 57 shows that with a cage-type mill, crushing a moderately hard bituminous coal, decrease in clearance

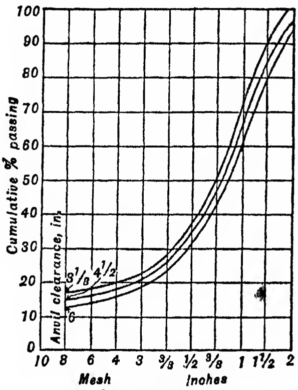

FIG. 56. Effect of anvil clearance on Impactor product (river gravel, $4^1/_2 \sim 1^1/_4$-in.; 420 r.p.m.).

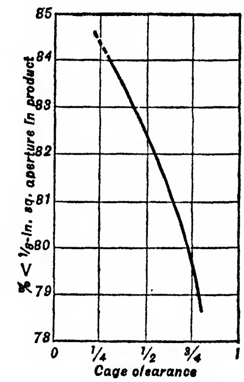

FIG. 57. Effect of cage clearance on size of bituminous-coal product.

has considerable effect on size of product. Fig. 58 shows the primary importance of high SPEED, particularly in the production of fines; the increase in fines is more than proportional to the increase in speed over the range investigated. Average speed is about 200 f.p.s. at the tip of new hammers, being, in general, somewhat lower for coarse feeds and coarse products and *vice versa*. This follows from the effect of particle size on striking force. Fig. 59 indicates that FEED SIZE has little effect on the amount of <100-m. in the product but that the limiting reduction ratio increases with increase in size of feed from about 2 for the finer feeds tested to 3 for the coarsest. The ratio of 50%-sizes (50% retained) is apparently largely dependent upon the smallest particles in the feed; for the conditions tested it was 5.5 for

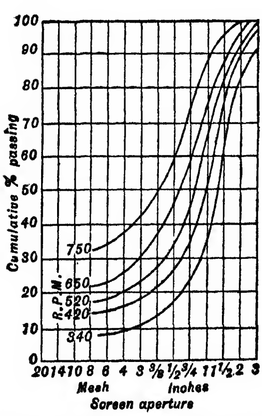

FIG. 58. Effect of speed on product of an Impactor (river gravel, $4^1/_2 \sim 1^1/_4$-in.).

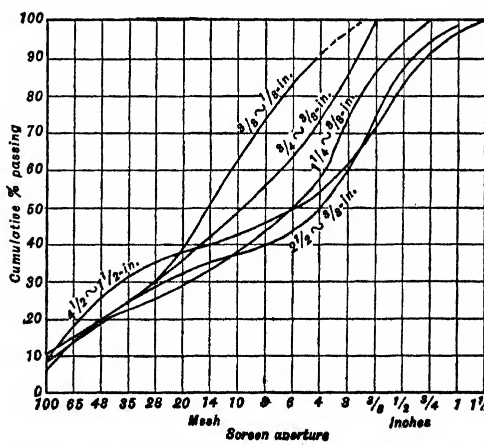


River gravel. Feed sizes shown on curves. 950 r.p.m.; 9 stirrup hammers; 9-ft. drop; 3-in. anvil clearance.

FIG. 59 Effect of feed size on size of product of an Impactor.

1/8-in. lower size, from 6 to 8 for 3/8-in. lower size, and jumped to 19 for 1 1/2-in. lower size. In so far as the 50%-point measures the average size of a comminuted product, the conclusion would seem to be that this type of mill is decidedly more effective in reduction of the coarser (1 1/2-in. min.) than the finer (1/8- and 3/8-in. min.) feeds.

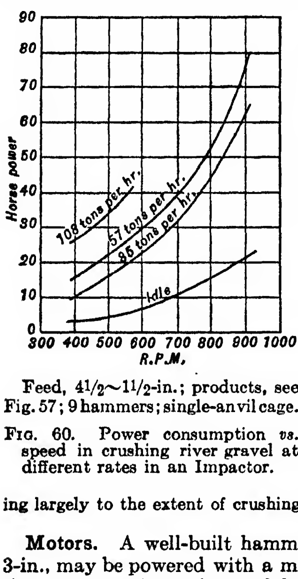
Mineralogical character of feed affects performance somewhat unexpectedly. In general hard tough rock crushes at a lower rate and requires more power than the complete converse, but reduction in

capacity with increase in power consumption with a given cage aperture and setting are reported in changing from Elkhorn to Pocahontas coals, and some clays are more difficult to crush than hard, compact limestones. The limiting machine factor is, in many such cases, the cage aperture and placing; it is probable that most of the discrepancies in reported results would disappear with suitable experimentation on this score.

Shape of product is of great importance in producing stone and sand for concrete work (see Sec. 3, Art. 41). Shape characteristics of products for different intermediate crushers have not yet been established generally.

At NORRIS DAM, crushing cherty limestone, <1/4-in. hammer-mill product was most nearly equiaxed, followed in order by rod mills, short-head cones, and rolls. The effect was more pronounced on the carbonate than on graywacke (*42 #6 RP 40*). An entirely different order of machines might be found with a different rock.

Power consumption in a hammer mill is dependent upon the amount of crushing work that the mill does, which, in turn, is determined primarily by the character of feed, the size of product, the speed, and the feed rate. Fig. 60 shows the relationship between feed rate, speed, and power consumption for one set of conditions; the trend is characteristic of all.



Feed, 41/2~11/2-in.; products, see Fig. 57; 9 hammers; single-anvil cage.

FIG. 60. Power consumption *vs.* speed in crushing river gravel at different rates in an Impactor.

The following data on crushing two bituminous coals at TOLEDO FURNACE (*PC*) in the same mill show that the effect of hardness of feed is not always what would be expected: Elkhorn coal (very hard bituminous), 168 t.p.h., 1.56 hp-hr. per ton, product 66% <1/8-in.; Pocahontas coal (very soft) 140 t.p.h., 3.3 hp-hr. per ton, 82% <1/8-in.; moisture was 3.9% in both cases. The probable explanation of reduced capacity with the softer coal is screen clogging, probably owing to the immediate shattering and rush to the screen; the rise in power consumption under such circumstances is caused by the resistance of material on the cage; that such a condition exists is indicated by the relative finenesses of product; the remedy would be to use larger cage apertures for the softer material. Effect of CAGE SPACING (distance from inner surface of cage to hammer circle) on power consumption is shown by the following runs on Elkhorn and Pocahontas coals at TOLEDO FURNACE: Elkhorn: close, 266 hp.; medium, 246 hp.; far, 220 hp.; Pocahontas: close, 220 hp.; medium, 204 hp.; far, 179 hp. Cage aperture was 1 1/2-in. in all cases; feeds were all rather wet. Usual motor allowance for mills crushing Pennsylvania bituminous coals to 70% <1/8-in. is 2 hp-hr. per ton; consumption ranges from 0.5 to 2.0 according largely to the extent of crushing, the moisture in the feed, and the sharpness of the steel.

Motors. A well-built hammer mill in secondary or fine service, with feed finer than 3-in., may be powered with a motor of not more than 15% overload capacity; if the feed size runs up to 4- or 5-in., peak loads will run 25 to 33% above normal full-load power draft; in coarse-crushing the power draft may fluctuate as much as in a jaw crusher (Art. 2). Recommended motor sizes are given in Tables 26 and 27.

Moisture in feed decreases capacity and increases power consumption markedly through the critical range in which fines are rendered sticky. With bituminous coal, capacity reduction is 30 to 50% and power increase about the same. The critical moisture range for most materials is about 6 to 10%. The cause is, of course, clogging of the grid. The remedy, if drying or further wetting is impractical, is to increase cage aperture or, if limiting size is important, to use a gridless machine and do the necessary screening on separate screens, better fitted for difficult separations, and where clogging will not cause excessive power consumption.

Feed rate should be regular; otherwise grid mills tend to clog on the rushes. In some grid mills in secondary service, especially with new steel and exceptionally coarse feed, the motors cannot be kept up to full-load power on account of incipient clog-up and consequent peak loads that tend to follow slugs of segregated coarse feed material.

Circulating loads vary materially with size of feed, feed rate, number of rows of hammers, extent of wear of hammers and breaking plates, moisture content, and resulting effect on screen efficiency. The fines returned from an inefficient screen tend to cut down crusher capacity, thus aggravating the circulating-load build up. Circulating load at NORRIS DAM with 1 1/2- and 2-in. grid spacing and 1/4-in. closing screen ranged from 50 to 100% of new feed; the circulating load all passed a 1-in. square hole.

Free fall of feed from feed chute to crushing zone determines penetration of hammer circle by the feed particles, and thereby affects both capacity and wear. If free fall is too

small, the particles are struck glancing blows, with resulting loss of impact and high wear on the outer edge of the hammers; if fall is too great, there is excessive wear on hammer shanks, rotor disks, and the shaft itself, and capacity is again low. The proper height, which depends, of course, on speed and on hammer shape, may be calculated from the theoretical formulas for gravitational fall with some assumed penetration. In the tests recorded in Figs. 54 to 58 it was found that a height calculated to give a 7-in. penetration resulted in even hammer wear and maximum capacity.

Maintenance in the form of renewals of hammers, anvils, and grids is a limiting factor in adoption of hammer mills. On highly abrasive materials in fine-crushing service hammers may require reversal several times per shift, whereas in intermediate crushing of soft limestones wear may be as low as 0.003 lb. per ton.

In crushing siliceous gravel the wear of Cr-Ni-Mo HAMMERS (450 to 500 Brinell) was 0.096 lb. per ton on 4 1/2~1 1/2-in. feed and 0.054 lb. per ton on 2 1/2~3/4-in. feed; consumption of manganese-steel hammers on the coarser feed was 0.063 lb. per ton, and on the finer feed 0.058 lb. Loss in weight of ANVILS (700 Brinell) in crushing 2,200 tons of gravel was 13 lb. from the hopper anvil, 16 lb. from the first cage anvil, 13 lb. from the second, 9 lb. from the third, and 8 lb. from the fourth, a total loss of 0.27 lb. per ton.

The importance of maintaining sharp corners on hammers is shown in Fig. 55. It is also important to maintain the edges of anvil blocks and of grate openings. Stelliting of hammers and bars, reversal of cage bars, and reversal and rerolling of plate cages well in advance of serious enlargement of aperture pay well in maintenance of capacity and reduction in power consumption.

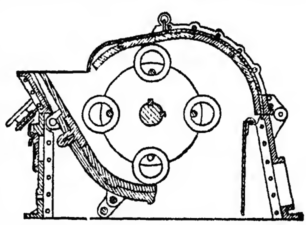


FIG. 61. Universal ring-type crusher.

Ring crusher (Fig. 61) is a modification of the hammer mill in which heavy rings instead of flailing hammer arms are hung on the disk pins or on short arms projecting therefrom. It is recommended by the makers for hard abrasive materials in intermediate or secondary service. The grate is eliminated in the form shown and the circuit closed by an outside screen, but grate forms are also made.

Symons impact crusher (*42 #3 RP 62*) comprises impact plates attached radially between and near the periphery of two parallel circular disks carried on a heavy horizontal shaft driven at high speed, and a heavy stop plate carried on the housing in such position that, with a central top feed, particles struck by the impact plates are thrown against the stop plates. The machine has no grate. It is recommended for secondary crushing of the softer materials. It is asserted that the rate of arrival at the stop plate is so high that particle-against-particle crushing occurs, and that the stop plate is correspondingly protected from wear. The impact crusher at COPPER RANGE (Sec. 2, Fig. 10) utilizes a similar principle.

10. STAMPS

Stamps are a mechanical form of the ancient mortar and pestle. Two types had long use, *viz.*, the piston stamp and the gravity stamp. A third type, actuated in various ways by crank or eccentric, appeared in many different forms, but was never widely used. Use of steam stamps has been limited, with the exception of a few experimental installations, to the native-copper mills of the Lake Superior district. Gravity stamps, which found their principal field in preparing ores for amalgamation, have not been excelled as machines in which amalgamation can be performed simultaneously with crushing. With the introduction of the cyanide process, particularly the all-slime process, finer grinding than could be performed economically in stamps became necessary; tube mills were installed for final grinding and the stamps were relegated to the position of intermediate crushers. In this service they come into unsuccessful competition with more efficient machines such as rolls, cone-type crushers, and ball and rod mills; their use at present is justified only in some of the older gold mills where replacement is clearly uneconomic, and for very small gold mills treating ores by amalgamation and/or gravity concentration (see Sec. 2, Art. 23).

Steam stamp (Fig. 62) consists essentially of a die resting in a mortar *a* with perforate walls, and a pestle *b* connected at the upper end with a piston rod *c* actuated up and down by a piston in a steam cylinder *d*. The mortar rests on a heavy metal anvil block which in turn rests on an enormous block of concrete. The steam end is carried on a frame *e* which is entirely separate from the mortar. The stamp stem is kept in alignment by guides *f*, carried on transverse supports attached to the legs of frame *e*. The steam end may be simple, cross-compound, or steeple-compound. Simple stamps are operated condensing, taking steam at 115 to 120 lb. per sq. in. and making 105 to 110 s.p.m. The usual steam pressures in compound stamps are 140 to 160 lb. per sq. in. in the high-pressure cylinder and 35 to 40 in the low. Exhaust steam from the stamps has been used, mixed with boiler

steam, if necessary, to run steam turbines. This is a considerable advance in steam economy. SHOE is made of chilled cast iron, weighs 750 to 800 lb. new and 300 to 400 lb. when discarded; life is 4 days to 2 weeks. The complete stamp stem, shoe, piston, and piston rod, weighs 5,500 to 7,900 lb. The lifting velocity is 8 to 10 f.p.s. and falling velocity 20 to 24 f.p.s. The striking force of the shoe is of the order of 25 to 50 tons. The MORTAR may be circular or rectangular. The bottom is protected by a false die on which the crushing die rests. LINERS and DIE are made of chilled cast iron. The die weighs about 800 lb. new and about 500 lb. when discarded. The life is 6 months to 1 year. SCREENS surround 50 to 75% of the periphery of the mortar above the liners. The usual height of the bottom of the screen above the top of a new die is 9 to 10 in.; with a worn die the height increases to 13 to 16 in. Screens are punched plate with $^5/_{16}$-in. to $^5/_8$-in. round openings. One panel is usually covered with screen having 50% larger apertures than the balance in order to pass copper that is free but cannot escape through either the finer screen or the HYDRAULIC DISCHARGE. The latter, in its simplest form, is an inclined pipelike opening through the mortar wall, up which water is introduced into the mortar at such velocity that only the largest particles of metallic copper can settle against the current. Another form has a small plunger jig, arranged to feed from a slot in the side liner just below the mortar grate. Either type will remove copper between $^5/_8$-in. and 4-in. size. Larger lumps must be manually removed; smaller pass the screens. The MORTAR JIG has a 1-in. screen and discharges fine copper from the hutch, coarse copper from the screen, and middling over the tailboard. The mortar rests on a solid cast-iron ANVIL BLOCK which in turn may rest either on hardwood spring timbers or directly on a concrete foundation slab. The latter increases capacity and lessens repair costs.

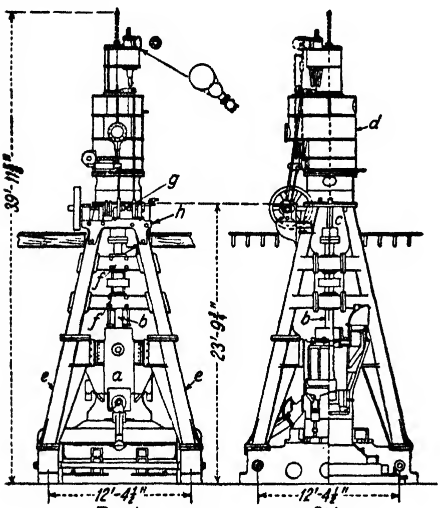

FIG. 62. Steam stamp.

Operation. Steam stamps are fed by hand through sloping chutes from feed bins containing <4-in. jaw-crusher product. The operator controls the flow by means of a hook or hoe so as to keep the thinnest safe layer of material on the dies. He picks mass copper, wood, and mine waste from the feed stream. Water is introduced with the feed and also through the hydraulic discharges. The total amount introduced is from 3 to 7 tons per ton of feed.

Performance. The capacity of a simple stamp crushing amygdaloid through $^5/_8$-in. screen at QUINCY is 450 to 500 tons per 24 hr., and the capacity of a steeple-compound in the same service at the same plant is 700 to 800 tons. When crushing amygdaloid through $^5/_8$-in. screen about 70% of the stamp product is less than half the screen aperture in size and 40% is smaller than 0.1-in. At CALUMET & HECLA a simple stamp crushed 350 t.p.d. of conglomerate from <3-in. through $^3/_{16}$-in. round screens, 0.07 ton per hp-hr.

Cost of crushing in steam stamps ranged from $0.15 to $0.30 per ton (1907).

Gravity stamp battery is shown in Fig. 63. The essential parts are the frame A, mortar block B, mortar C containing die D on which ore is broken by a pestle composed of shoe E, boss head F, stem G, and tappet H. The pestle is lifted through the tappet by means of cams I carried on cam shaft J driven by pulley K and belt L from pulley M on countershaft N. Ore to be crushed passes from the bin O through the automatic feeder P to the mortar and is discharged, when fine enough, through screen Q. Stamps are rated on the weight of the falling part. The usual weights in American mills are from 1,250 to 1,500 lb. In South Africa 1,500- to 2,000-lb. falling weights are more usual. Old California practice was to use 850- to 1,050-lb. stamps and many of these are still found.

Weight of a complete 5-stamp battery, excluding wood of frame, ranges from 20 times the weight of an individual stamp for batteries under 1,000-lb. falling weight to about 15 times for heavy stamps. Of this total, the weight of the falling parts and mortar is about 55 to 65% for stamps under 1,000-lb. increasing to 75 to 80% for the heaviest stamps.

Frames are commonly made of timber, but cast iron, structural iron, and reinforced concrete have also been used. Timber frames: Main posts are commonly 12×24-in. or 12×26-in.; sills and girts 10×12-in. or 12×12-in., and guide timbers 12×12-in. and 12×14-in.

Mortar commonly holds five dies. A typical mortar is shown in Fig. 64. Weight ranges from 6 times the falling weight with light stamps to 9 or 10 times with heavy stamps. The narrow, straight-backed mortar shown in Fig. 64 is designed for rapid discharge and high capacity. It is cast roughly as a deep box with feed opening A at the back and discharge opening at the front. The screen C is held in the discharge opening by means of wedges D which press the screen frame tightly against planed surfaces on the mortar. Chuck blocks E, held in place by wedges, are inserted for the purpose of varying

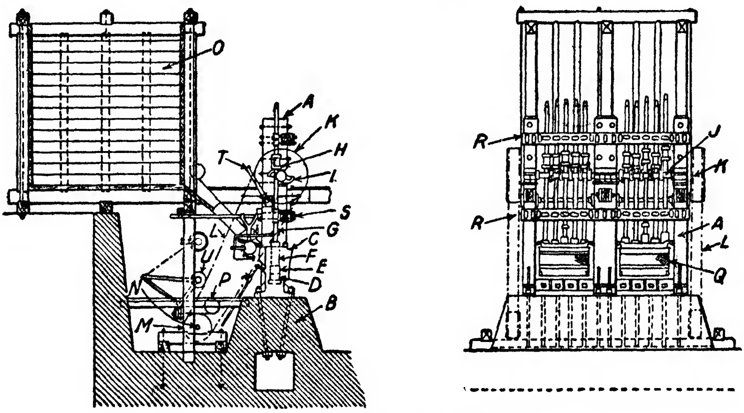

Fig. 63. Typical 10-stamp battery.

the height of the screen. Where amalgamation is practiced it is usual to mount a copper amalgamating plate F on the chuck block in order to catch some gold in the battery. A wooden cover G to prevent splash rests on a shelf cast on the walls of the mortar. It is provided with holes for the stamp stems. Liner plates H in the feed chute, sides, and ends protect the casting from wear and are easily replaceable. Amalgamating mortars are wider and are provided with a rear amalgamating plate as well as a chuck-block plate; provision is made by means of a removable cover for access to the back plate without lifting the stamps. Crushing is not so rapid as in the narrow mortar; such a mortar is used when amalgamation in the battery is more important than rapid crushing. Feed opening usually extends the length of the three center stamps but in some mortars is made full length. Feed is supplied in a narrow stream at the center and is distributed by the swash of pulp. Design of a mortar has considerable influence on operation. With ores containing minute particles of rusty gold which require burnishing before amalgamation can be accomplished, fine grinding is necessary and a wide mortar with back and front plates and a fine screen should be used, if the battery is depended upon for all of the crushing. With a free-milling ore containing coarse gold that is easily separated from the gangue, a narrow, single-discharge mortar is properly used. This mortar should also be used where the purpose is high capacity, and later machines are depended upon for completion of the grinding. The limit of narrowness is imposed by the requirement of a space between the dies and front and back walls greater than that of the largest particles of feed in order to prevent wedging therein with consequent strain on the stem. For maximum capacity with minimum stem breakage the back should be about 2 1/2 in. from the back of the dies and the screen about 5 1/2 in. from the front of the dies. The slope of the back is set at about 75° from horizontal and the screen at 75° to 80°. Average life of 5,500-lb. mortars at HOMESTAKE (4.5-ton stamp duty) was 3 years.

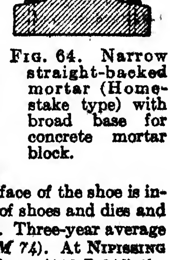

Fig. 64. Narrow straight-backed mortar (Homestake type) with broad base for concrete mortar block.

Sectional mortars are made for shipment into inaccessible regions. The sections are made so that no piece much exceeds 300 lb. weight. Stems are made somewhat lighter than standard to go with sectional mortars, and a hollow cam shaft is likewise furnished.

Dies (Fig. 65) are inserted in the bottom of the mortar. They are made of chilled cast iron, semi-steel, forged steel, chrome steel, and manganese steel. Normally the shoe and die are made of the same material. It is good practice to replace dies before they are worn to full depth, for the reason that the surface becomes very irregular with wear and that crushing efficiency is thereby lost. By making dies 1/4 in. larger than the shoes, contact of the shoe with the die over the whole face of the shoe is insured even after considerable stem and die wear. This makes for more even wear of shoes and dies and higher crushing duty. Average LIFE for solid dies on ordinary ores is about 60 days. Three-year average for hard cast-iron dies at HOMESTAKE (900-lb. stamps) was 30 to 35 days (*28 IMM 74*). At NIPISSING (*48 A 13*) forged chrome-steel dies lasted 130 days with very hard tough ore; at SUAN (*119 P 916*) the same material lasted 100 to 120 days. At CHURCHILL-WONDER (*52 A 128*) the consumption of forged chrome-steel dies on hard tough quartz was 0.107 lb. per ton crushed through 3/8-in. screen. At RAINBOW chrome-steel dies lasted 100 to 120 days with 1,050-lb. stamps crushing through 4-m. Consumption of cast-iron dies at ALASKA TREADWELL (*102 J 68*) was 0.17 to 0.24 lb. per ton crushed. At ZARUMA, Ecuador (*111 J 583*), the consumption of chrome-steel dies was 0.12 lb. per ton.

Shoes (Fig. 65) are made of cast iron, chilled iron, cast steel, forged steel, chromium or manganese steel. Common practice is to use forged or alloy steel. The shank of the shoe fits loosely into a cored recess in the bottom of the boss head and is wedged in by means of hardwood wedges which swell when wet and make a firm joint. In dry crushing, steel wedges are used. WEAR OF SHOES averages from 60 to 90 days for forged- or chrome-steel shoes working on medium ores. The 3-year average for chilled cast-iron shoes on 900-lb. stamps at HOMESTAKE was 60 to 90 days (*22 IMM 74*). Forged chrome-steel shoes at NIPISSING lasted 105 days (*48 A 13*) and at SUAN 100 to 120 days (*119 P 916*). Consumption of the same material at CHURCHILL-WONDER (*52 A 128*) crushing hard tough quartz through 3/8-in. screen was 0.232 lb. per ton. At RAINBOW (*99 J 1104*) the life of chrome-steel shoes was 80 to 90 days with 1,050-lb. stamps and 4-m. screen. Consumption of chrome-steel shoes at ALASKA TREADWELL (*102 J 46*) was 0.37 to 0.41 lb. per ton of ore crushed. At ZARUMA (*111 J 683*) the consumption of chrome-steel shoes was 0.29 lb. per ton.

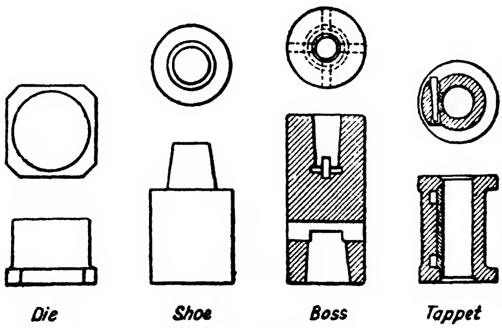

FIG. 65. Stamp parts.

Boss head (Fig. 65) forms the link between stem and shoe; it is made of cast iron, cast steel, or chrome steel, cored out at the bottom to receive the shank of the shoe and bored to a taper at the top for receiving the tapered end of the stem. Slots are cored at right angles at the bottom of the tapered openings to receive drift keys for driving out the stem and shoe. Life is indefinitely long and is terminated by breakage.

Stems are made of hammered iron or mild steel, turned and polished and tapered both ends so as to make them reversible in case of breakage. Amount of breakage depends upon the length, the location and condition of guides, and the weight of the tappet. Long stems with heavy tappets and worn guides break in a short time whereas under reverse conditions breakage is almost unknown. Steel and occasional large lumps in the feed cause eccentric strains that produce much breakage. The break usually occurs near the boss. Broken stems are turned end-for-end. Broken ends may be turned down and the stem again used, if not too short. Annealing before turning down will defer subsequent breakage. In starting, the center stamp should be started first to save pounding on empty dies with consequent stem breakage. Average life at HOMESTAKE over a 3-year period for wrought-iron stems 3 1/8-in. diameter was 4 months. Mild-steel stems 3 7/16-in. diameter at SUAN, Korea (*119 P 916*), on 1,050-lb. stamps lasted 4 years. TAPPETS (Fig. 65) are made of cast iron, cast steel, or alloy steel. The purpose of the tappet is to convert the rotary motion of the cam-shaft into rectilinear motion of the stamp. They are clamped to the stem by a gib pressed tight by keys driven through the keyways shown.

Cams, mounted on a shaft, working against the tappets, lift and drop the stamps. Cams are made two-armed and are ordinarily designed to lift the stamps at constant speed; material is cast iron with chilled faces, or cast or special steels. It is important that cams be closely designed for the required drop length. Life is indefinite. Breakage is normally due to CAMMING, *i.e.*, pick-up of the tappet by the cam before the stamp has completed its fall. This is caused by too long stroke or too many strokes per minute.

Height of drop may be varied within small limits, with a given cam, by changing the position of the tappet on the stem. The amount of variation is, however, small, if the tappet is to be picked up at the place on the face of the cam designed for this service. As dies and shoes wear, the height of drop is kept as nearly constant as possible by changing the position of the tappet on the stem to compensate for wear. In general, the height of drop of the stamp in front of the feeder, usually the center stamp, is made about 1 in. greater than that of the others on account of the greater depth of ore at that point. The height of drop of the end stamps is likewise normally made somewhat greater than that of the adjacent stamps in order to overcome the tendency for the ore to pile up in the ends of the mortar.

Drop sequence. Cams are spaced at equal intervals on the cam-shaft, 36° or 72° apart, depending upon whether the shaft carries 10 or 5 cams. Sequence of drop has a marked effect on performance. The following rules governing sequence have been set down: (1) No two adjacent stamps should fall in succession. (2) When one stamp is falling its neighbor should be rising. The common sequences, aimed to satisfy this rule, are the HOMESTAKE, **1, 3, 5, 2, 4** (numbering from either end), which, stated backward, is **1, 4, 2, 5, 3**; CALIFORNIA, **1, 4, 2, 3, 5 = 1, 5, 2, 4, 3**; and modifications of the latter such as **1,5,3,4,2**; and **1,5,3,2,4.** The sequence **1, 3, 5, 2, 4** comes nearest to satisfying the theoretical requirements, but many operators claim that the California sequence gives better distribution of pulp on the dies and a swash of pulp in the battery that is better fitted to cause material to pass through the screen. When a 10-stamp battery is used the sequence 1, 3, 5, 2, 4 becomes **1, 7, 3, 9, 5, 2, 8, 4, 10, 6** and 1, 5, 2, 4, 3 becomes **1, 6, 5, 10, 2, 7, 4, 9, 3, 8.**

Cam-shaft is made of a diameter sufficient to withstand the bending stresses imposed by the weight of the cams and the lifting shocks, when supported over a span equal to the distance between the main posts of the frame. It is made of a metal that will withstand the tendency to crystallization brought about by repeated shocks. Mild steel or iron, hammered out and turned to the desired diameter, are the usual metals. Diameter ranges from 5 to 8 in. according to the weight of stamps. Life is from 6 months to 5 years.

Pulley is subjected to heavy service, and experience has shown that this service is best withstood by a built-up wooden pulley; cast-iron pulleys will not stand the strain. Pulleys are finished 7- to 8-ft. diameter by 16- to 20-in. face.

Screens are made up by tacking woven wire or punched plate to heavy wooden frames. Discharge is dependent upon the type of perforation, percentage of opening, and size of opening. Punched plate is thin, quick-discharging, and cheap; if heavy enough to withstand breakage, it is probably the best available, but with narrow, high-discharge mortars failure by breakage is excessive; for heavier service slotted punched plate is used; for high capacity with coarse discharge, woven wire, which has a greater percentage of opening than plate, is used. Capacity requirements dictate screens of moderate weight even though such practice involves more frequent replacement. LIFE of screens is extremely variable; it ranges from 2 or 3 days to perhaps 2 weeks for fine screens and from 2 weeks to 2 months for coarse screens.

Prospecting mills. Most manufacturers make 1-stamp, 2-stamp, 3-stamp and 5-stamp prospecting mills with stamps ranging in weight from 250 to 450 lb., sectionalized so that no piece exceeds 300 to 350 lb. weight. Such mills require from 2-hp. to 6-hp. engines with boiler rated at 25 to 33% in excess of the engine. The boiler will weigh so much more than any part of the stamp that much of the advantage of sectionalizing is lost.

Duty is the tons crushed per stamp per 24 hr. Reported duties range from 1.8 for a 750-lb. stamp crushing through 30-m. screen to 21.1 for a 1,550-lb. stamp crushing through 1/4-in. screen. Duty depends principally upon character of ore; size of feed and product; weight, speed, and drop of stamps; shape of mortar; and condition of shoes and dies. Size of feed should not exceed 12-in. for hard ores with medium-weight stamps. Increase in screen aperture over the range of 28-m. to 1/4-in. increases capacity about 2 1/2 times but makes relatively little difference in the tonnage of fines produced.

Height of discharge is the vertical distance from the top of the die to the top of the lower rail of the screen frame. The height of discharge increases as the dies wear. In order to keep it constant, as should be done, chuck blocks of different heights are provided which vary the height of the screen above the bottom of the screen opening. For closer regulation slats 1 to 1 1/2 in. thick are used between the bottom of the screen and the top of the chuck block. The height of discharge may also be varied by use of a false bottom under the dies, but this practice is not favored because of the effect on the character of impact. High discharge results in low capacity and fine product and *vice versa*. The effect is least with fine screens

Height of drop. The amount crushed per drop increases with increase in height of drop in substantially direct proportion, but since a short drop permits more drops per minute, development was toward heavy high-speed stamps. High drop causes greater splash in the battery and, therefore, more rapid discharge.

Speed. The amount crushed per unit of time increases directly with the number of drops per minute. Number of drops per minute and height per drop are interdependent; if the height of drop is lessened, the time for completion of a cycle is decreased and the number of cycles or drops per minute can be increased. The force of the blow struck by the falling stamp can then be kept up by increasing the weight of the stamp. Average practice is 100@ 6- to 8-in. drops per min.

Power for stamps varies with the weight of stamp, height of drop, and number of drops per minute. The theoretical power required may be calculated by the formula Hp. $= WHN/(12 \times 33{,}000)$, where W is the weight per stamp in pounds, H is the height of drop in inches, and N is the number of drops per stamp per minute. The total theoretical power for a battery is this figure multiplied by the number of stamps. The actual power consumption exceeds the theoretical by 16 to 70%. An allowance of 25 to 30% excess is safe for purposes of estimate. Tons crushed per hp-hr. averages 0.074 with battery screens finer than 0.05-in. aperture, 0.138 for apertures from 0.05- to 0.25-in., and 0.164 for apertures coarser than 0.25-in. Truscott is quoted *(111 J 200)* to the effect that South African performance averages 0.05 ton per hp-hr. from $<$2-in. through 30- to 40-m. screen, 0.1 ton through 12- or 16-m., and 0.2 ton through 3- or 4-m. These figures are of the same general order as the preceding.

Moisture in product ranges from 75 to 95%. The quantity of water used per ton is less with coarse screens than with fine and less the smaller the height of discharge. The Challenge feeder (Sec. 18, Art. 22) is most commonly used; it is the most satisfactory, especially on wet and sticky ores.

Cost of crushing in gravity stamps ranges from $0.15 to $0.50 per ton.

Nissen stamp unit consists of a single stamp falling in an individual mortar which is cylindrical in horizontal section. Two stamps mounted in a frame similar to that used with the 5-stamp battery constitute a unit and require about the same floor space as one 5-stamp battery. The screen extends more than halfway around the mortar and has an area of 3.75 sq. ft., which is about 3 1/2 times as much per stamp as in an ordinary single-discharge 5-stamp battery. The mortar is made of semi-steel with manganese-steel liners. The total weight of a steel-frame battery ranges from about 10 times the falling weight for a 1-stamp unit to 5 times for a 4-stamp unit. Results of competitive runs with standard stamps were generally in favor of the Nissen.

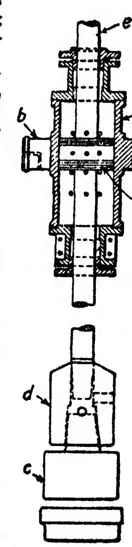

FIG. 66. Pneumatic stamp.

Pneumatic stamps, also called CRANK STAMPS and HIGH-SPEED STAMPS, have had limited use. The Holman (Fig. 66) is the best known. It consists essentially of a cylinder *a* attached by means of trunnions *b* and connecting rods to the driving mechanism. A crushing member consisting of shoe *c* and boss-head *d* is mounted on the lower end of a piston rod *e* that runs through the cylinder and carries piston *f*. Air ports are provided in the cylinder walls, one set for use with new shoes and

dies, the other when shoes and dies are half worn. The piston itself acts as a valve, closing the lower ports on the upstroke and the upper ports on the downstroke, thus providing air cushions that protect the cylinder heads. The stamp is run at 120 to 140 @ 12-in. s.p.m. and requires from 30 to 35 hp. per unit of two stamps.

Performance. At EAST POOL, Cornwall (*86 J 213*), one 2-stamp unit crushed 21 tons per 24-hr. of <3-in. feed through a 25-m. screen. The capacity of a 950-lb. gravity stamp on the same feed is 1.4 to 1.5 tons per 24 hr. At MOUNTAIN QUEEN, West Australia (*95 J 108*), a 2-stamp unit crushed 135 to 160 t.p.d. of fairly hard ore through a 10-m. screen. Metal consumption was 0.45 lb. per ton; water, 1,200 gal. per ton. At BABILONIA GOLD MINES, Nicaragua (*113 P 911*), a 2-stamp unit making 145 to 150 drops per min. crushed <2.5-in. feed through 6- and 9-m. wire screens at the rate of 25 tons per stamp per 24 hr. Water consumption was 9 tons per ton of ore. Mortar liners lasted 4 months, stems 3 months, screens 3 days. Wear of shoes was 0.48 lb. per ton and of dies, 0.17 lb. per ton. The product contained 50% >20-m. and 12% <200-m.

11. MISCELLANEOUS METHODS OF BREAKING

A variety of methods of breaking are used, more or less infrequently, accessory to the continuous machine breaking described in the foregoing articles. Most of them are intermittent, and are practiced only when some circumstance of the continuous plant renders it unavailable for the particular service.

Sledging is a common expedient for breaking lumps too large to enter the primary crusher, or to pass through storage ahead of the primary crusher. The usual arrangement for sledging is a horizontal grizzly on top of a bin, but a floor is safer and more efficient. The sledging done is usually confined to the minimum that will permit the lumps to be worked through the grizzly. Sledges are 10- to 16-lb. double-faced hammers with handles ordinarily 30 to 36 in. long; occasionally one end of the head is a wedge-shaped peen with the edge either parallel or at right-angles to the handle; such heads are of considerable utility in the hands of a skillful operator, but are difficult to handle. DUTY of a man sledging is highly variable and substantially impossible to measure. Usual practice is to mine in such a way that one topman on the bin can do all necessary sledging in connection with his other duties; if this is impossible, the economics of the situation quickly forces a change in the primary-crushing installation.

Spalling is breaking of 6- to 8-in. lumps to 2- or 3-in. size with light 2- to 3-lb. long-handled hammers having rounded peens. It is practiced only in primitive operations where labor is cheap. DUTY of a man is stated to range from 250 to 1,500 lb. per day.

Cobbing is breaking with short-handled hammers weighing 2 to 4 lb. Lumps cobbed are rarely larger than 6-in., usually 2- or 3-in. and smaller. It is practiced in primitive mills in connection with hand picking; cost is prohibitive if wages are more than 50¢ to $1 per day.

Mud-capping; blockholing. These are methods of breaking large lumps by blasting. Mud-capping consists in setting a small charge of dynamite (1/4 to 1 lb.) on top of the boulder, preferably in a depression in the surface, placing a blasting cap on top of it, covering the charge with as much mud as can be made to stay in place, and firing. In blockholing, a shallow hole is drilled in the boulder to hold the charge of explosive. Gillette (*Peele*) gives average cost per cyd. for blockholing as 17¢ and for mud-capping as 31¢, and states that both methods are much more expensive than sledging.

Mechanical hammers of the pile-driver and dropped- or swinging-ball type are occasionally used for breaking boulders in dredge pits. The pile-driver type was used to some extent in the days of mass-copper ores at the Lake Superior mines; the hammers weighed 1,500 to 2,000 lb. and were dropped 5 to 20 ft. according to the blow desired.

Heating and quenching have been practiced for breaking rocks since time immemorial. Where wood fuel is cheap, Gillette (*Peele*) places the cost of thus breaking boulders at about 15¢ per cyd., *i.e.*, less than blockholing. Richards (*OD*) cites a number of cases of heating prior to crushing in order to render rock more friable.

At BRIDGEPORT WOOD FINISHING CO., grinding quartz to a high-purity guarantee, the initial break from cobble-sized rock was made by heating to redness in a dumping furnace and then quenching in a tank of cold water; the broken product, 2- to 3-in. limiting size, was sufficiently cracked to permit secondary reduction in stone-tired Chilean mills.

Some alloys become sufficiently brittle at temperatures possible to maintain in crushing machines to permit breaking by the usual methods.

Explosive shattering is a name applied by the Bureau of Mines to a method proposed by the Bureau as a possible competitor of present commercial methods of crushing (*RI 3118, 3201; 136 J 281*). It consists essentially in subjecting the rock to be crushed to steam at a pressure of 250 lb. per sq. in. and upward for a short interval of time (*e.g.*, 2 sec.) and then releasing the pressure suddenly, whereupon the charge is ejected against an impact

plate. Experiment indicates that much of the crushing done is due to impact, but that elimination of impact (discharge against rubber) still leaves an appreciable amount of breaking, which is attributed to failure along crystal planes and the like as the result of an explosive wave. There is distinct preferential breaking as between certain minerals. The method has not had commercial use but has been mentioned in connection with one of the Bureau-designed wartime pilot plants.

12. CRUSHING PLANTS

A crushing plant comprises an integrated combination of crushing machines, sizing apparatus, storage, feeding and transport means, and sampling and control devices, the whole designed to receive rock at the sizes, rates, and times prescribed by the exigencies of the excavating operation, and to deliver a product or products sized, situated, and timed according to consumption demands. The sizes of the various machines and apparatus, and their number, differ greatly according to receiving and delivery conditions; their arrangement is dependent upon their size, the topography, and the areal spacing of the source of rock and the point of delivery of finished product. Yet despite the multiplicity of combinations of supply and delivery demands that are possible, a small number of relatively definite plant patterns has been developed, one of which, with minor variations, will satisfy almost any conceivable requirements.

Elements of a crushing flowsheet are: (1) Receiving unit; (2) primary-crushing unit; (3) secondary- or intermediate-crushing unit; (4) fine-crushing unit; (5) storage. Transport, sampling, and control are accessory; they vary in apparatus detail much more than do the elements.

Receiving comprises the means for transfer of material as excavated from the source to and into the primary crusher. It always involves some method of transportation the characteristic of which is intermittency, since the normal methods of transport from the excavation are cars, trucks, or skips, *i.e.*, discrete containers of considerable volumetric capacity. The nature of the receiving unit as a whole depends upon the necessity or desirability for some separation ahead of primary crushing, and upon the price that the designer wishes to pay at this point for uniform flow through the plant.

If hourly tonnage is small, the primary-crushing units are ordinarily correspondingly small, and some means of ironing out rushes of feed is immediately necessary. The usual expedient is a receiving hopper or bin. This is normally provided with a regulable discharge over a surface that permits rapid selection of extraneous waste such as steel, timber, rope, and dynamite. With small tonnages, primary crushers usually have small receiving openings, hence it is necessary to place a size guard at some place in the path from the excavating face to the crusher, *e.g.*, a flat grizzly over the receiving bin (see Sec. 14); this then serves also as the surface for selection of waste, as above.

If hourly tonnage is great, large primary-crushing units are employed. These can operate buried. In this case the transportation system is utilized to afford such storage as is necessary to bridge the difference in capacity of excavation and primary-crushing units, while removal of waste, if practiced, is deferred until after primary crushing.

Storage ahead of primary crushing is always troublesome because of the difficulties involved in flowing coarse material. If the crude is wet, there is the additional difficulty caused by freezing in cold weather. Hence crude storage, if necessary, is designed to interrupt flow as little as possible. If, despite such design, hang-ups caused by freezing, or packing of wet material, or bridging of coarse material occur, special provisions must be made for prevention (Sec. 18, Art. 4).

Scalping out fines from the feed to the primary crusher should be a part of the receiving plant whenever this is structurally convenient, since fines in crusher feeds increase power consumption and maintenance, and ordinarily reduce capacity. The usual scalping device is a grizzly (Sec. 7, Art. 4), the normal aperture of which is equal to the open setting of the primary crusher; aperture may be made larger, however, if it is desirable to take some burden off the primary crusher and if the secondary has excess capacity.

Feeding. Any crusher operates most efficiently when fed uniformly at a rate near maximum capacity. This requires some means of regulating flow to the machine. The usual arrangement is a feeder with push-button start-stop control under the supervision of the primary-crusher tender. The feeders are ordinarily of pan, apron, or vibrating, chain, or single- or multi-roll type (Sec. 18, Art. 22). They permit picking of extraneous waste as an incident to control.

Weighing on platform scales (track or road type) may be a part of the receiving operation; it is not of much value, however, unless accompanied by moisture sampling, which is substantially impossible with coarse primary feeds.

Primary-crushing unit is, almost invariably, one single crushing machine, since a crusher tender is always necessary for each primary machine. Preferably the receiving opening is large enough to take any lump that can be handled out of the mine, thus eliminating the

expensive operation of guard sizing from the receiving unit. The machine must be sufficiently rugged and powerful to break any lump of feed without over-strain; it is desirable that it have sufficient capacity to break at the maximum rate of mine production, thus eliminating the necessity for storage in the receiving unit. If, additionally, it can work buried, and pass any steel or timber that may come in the normal run of mining operation, it approaches the ideal.

Type of crusher. Jaw and gyratory crushers are used as primaries for hard rocks; they are available in sizes large enough to receive any lumps that can be mined by present methods, and to crush them at almost any desired rate.

The only existing mine with excavating capacity and maximum product demand in excess of the capacity of a single primary crusher is UTAH COPPER CO. There, since the demand for copper is fluctuating, two parallel mills were built, permitting complete shutdown of one in times of reduced demand. Thus the primary-crusher problem was solved as a part of the larger problem. Actually, also, the limit in receiving-unit capacity (see Sec. 2, Fig. 18) was reached at least as soon as the limit of crusher capacity.

For choice between jaw and gyratory crushers see Art. 4.

Single-roll crusher is used as a primary for the softer rocks (limestones, etc.). It likewise is available for all necessary reception and capacity demands. It is superior to jaw and gyratory crushers for ores that tend to pack under pressure, because the slugger teeth also act to push material through the breaking zone.

Hammer mills, preferably without grates, are used as primaries for very soft materials (*e.g.*, clays).

Cone crusher is a suitable primary when, as at MIAMI (Sec. 2, Fig. 22), the mining method is such that the largest lump is receivable by this machine. Capacity available in a single machine is, however, less than that of the usual primary (*cf.* Tables 1, 12, and 20), so that the utility of the machine in primary service is limited on this score.

Secondary-crushing unit presents a number of problems entirely different from those met in the primary unit. Individual machine capacities are much lower than those of the primaries, so that more than one unit must often be employed, with the resultant problem of distribution of feed. Scalping out fines ahead of the crushers becomes a necessity, if the ore is damp or clayey, and is, in any case, highly desirable. Uniformity of feed rate is essential for the best operation. If the secondary unit is also the final unit, a sizing guard on the product is ordinarily necessary, with provision of transporting means for return of oversize. The machines must be guarded against tramp iron, and frequently against other extraneous waste. Finally, it is desirable that the unit should favor the production of fines or the reverse, according to whether the final products wanted are sand and slime, or gravel sizes. Thus the secondary unit comprises, in addition to the crushing machine, screening, distributing, storage, feeding, separating, and transporting means, all suitably integrated to the particular job.

Crushers are usually cone-type in the hard-rock mills, particularly if the secondary unit is not the final unit; in soft-rock plants they are ordinarily hammer mills. For rocks of intermediate hardness, either cone-type or impact machines may be used, the choice being resolved in favor of the cone-type when capacity and operating cost are the primary considerations, and in favor of the impact type when shape of the fragments is important (see Sec. 3, Art. 41). The hammer mill is also materially cheaper in first cost than a cone-type machine of corresponding capacity.

Clogging due to wet or sticky ore is, of course, more common in secondary and fine crushers than in primaries. The usual expedient, when it is allowable, is to turn water into the circuit. This invariably increases capacity, but it also increases steel consumption markedly, owing, no doubt, to increased oxidation. At FRESNILLO (*112 A 735*) a clay-bearing oxidized ore becomes so sticky in rainy weather that the capacity of the crushing plant is, at times, reduced to less than one-third of normal. Remedies attempted are to open up the crusher throat and try to keep material moving with water and with high-pressure air. At MATAHAMBRE (*IC 6544*) primary-crusher product was immediately screened to the finishing size of the crushing plant ($<^3/_4$-in.); otherwise the sticky fines caused trouble in all subsequent crushing and screening (see Sec. 2, Fig. 14). At ENGELS (*IC 6550*), wet, sticky ore required 3 to 4 men in a 100-t.p.h. crushing plant, one on the primary crusher, one on conveyors, and one or two on bin outlets.

At BRITANNIA (*IC 6619*) clogging in rolls was mitigated materially by placing washing screens ahead of the rolls, and closing the roll circuit through the same screens.

Screening, whether for scalping only or to guard the product as well, is ordinarily done by one screen, which is in closed circuit if a guard screen, but otherwise in open circuit and serving merely as a by-pass for fines. Vibrating screens are almost invariably used in the concentrating mills. In rock-product mills making multiple sizes, trommels or the flat-slope shaker vibrators, fitted with screen sections of successively larger apertures, may be used instead of multiple-deck vibrating screens because they additionally transport and distribute their products. If scrubbing is necessary, revolving screens are almost always used, but light washing can be done satisfactorily on a vibrating or shaking screen.

Closed circuits. It is well established that production of sizes smaller than 10-m. is much less efficiently done in crushers than in tumbling mills. It follows, therefore, that when crushing to <10-m., any undersize sent back to the crusher from the guard screen is going to be comminuted, if at all, less efficiently than otherwise could be done. When the guard screen is coarser than 10-m., return of finished undersize caused by screen inefficiency is an almost complete waste of power. At the same time it takes

up space in the crushing zone that might otherwise be occupied by new feed. It consumes power almost in proportion to its volume. Hence ample screening capacity and efficient screens are essential to efficient closed-circuit operation.

Circulating loads in roll circuits range normally between 100 to 300%; they may run as high as 700% with a 10-m. closing screen, but the economy of so large a load is questionable. Circulating loads in closed circuits with fine-crushing short-head cone crushers tend to run upward of 500%; the economy of such an installation is highly doubtful, but sufficient data are not available for final decision.

Storage and distribution. If the tonnage passing the primary breaker per unit of time is in excess of the capacity of a single secondary crusher, it is necessary either to store a part of the primary-discharge stream or to split the stream into two or more parts, according to the number of secondary crushers required to keep up with the primary. Splitting a running stream of relatively coarse rock into two streams of equal tonnage and size composition is difficult, although it can be approximated by causing ths stream to fall onto a vertical edge placed at right angles to the width of the stream and on its center line. It is impossible to split into more than two equal streams at one operation, or to split into an odd number of equal streams by any practicable number of operations. Hence it is usual, if more than two secondary crushers are required to keep up with the primary, to stop the stream in a bin, which, if properly designed, and equipped with suitable loading and unloading arrangements, can deliver any desired number of substantially equal streams. Use of a bin has the further advantage of ironing out the almost inevitable surges in primary-crusher discharge rates, and permitting uniform maximum loading of the secondary crushers. If secondary-crusher feed is scalped, it is customary to place the scalping screen high enough to feed the distributing bin by gravity. Bin size depends upon the storage time that must be provided, upon the number of streams to be taken off and the horizontal spacing of the take-off points, and upon the tendency for the material to segregate in entering the bin (see Sec. 18, Art. 2).

Removal of extraneous waste. Magnets are used to remove iron (except in mills treating highly magnetic ores). For types of magnets applicable see Sec. 13. It is practically imperative to remove coarse iron from the feed to cone-type crushers, and highly desirable that it be removed from the feed to all secondaries, since tramp iron is one of the primary causes of stalling and/or breakage of crushers not properly guarded. High-manganese steel is nonmagnetic, hence shovel teeth and the like, of this material, must be removed by other means.

Wood, rope, and the like, if present in harmful quantities and not removed ahead of the primary crusher, are removed by hand picking from the stream leaving this crusher. For suitable arrangements see Sec. 14, Art. 2.

Transport of crushed rock throughout a crushing plant is ordinarily done by belt conveyors (Sec. 18, Art. 6); the exceptions are the use of pan conveyors (Sec. 18, Art. 7) for short runs of coarse material at low speeds (as for hand picking), or on slopes too steep for a belt; and the rare use of bucket elevators (Sec. 18, Arts. 12 to 14) when lateral space is lacking for gaining the required elevation by belt conveyors, or the use of conveyors for elevation is, for some reason, considered impractical.

Feeding. Final delivery to secondary crushers is almost always done by a chute, the portion of which overlying the crusher is made readily removable to facilitate access to the crusher for repairs Original feed from a bin is effected by any one of several of the feeders described in Sec. 18, Arts. 22 and 23, according to the requirements of the case. For the simple case requiring only transfer out of the bin at a reasonably constant rate, apron feeders with gate or swinging-hammer control of stream thickness are ordinarily used for the coarser feeds, and belt feeders for the finer.

Fine-crushing unit presents an even more complicated problem than the secondary unit, and the answers are not so well established. The crushing machines themselves are of lower capacity than the secondary crushers; they are more sensitive to variations in size, mineralogical character, moisture content, and rate of feed; their operation is more costly; there are more varieties available; and their duties are more varied and more closely specified. Scalping and guarding the product are more frequently and urgently necessary in most fine-crushing plants than in the secondary units. On the other hand, transport, distribution, and storage are normally simpler, and waste removal is less pressing, if a good job has been done on this score in the primary and/or secondary units.

Crushing. The purpose for which the crushing is done, the prescribed maximum size of product, and the tonnage are the prevailing elements in selection of the fine crushers. In concentrating mills preparing feed for flotation, the size specification for final crushed product (grinding-plant feed) is normally between 3/8-in. and 10-m. With the usual abrasive ores this substantially narrows the choice of machines to short-head cones or rolls. Practice has largely resolved the competition between the two in favor of the short-head for a product <1/4- to <5/16-in. or larger, rolls being generally used for finer products. Recently rod mills have displaced rolls in the fine-product field in some hard-rock service (see Sec. 5, Art. 7, and Sec. 2, Figs. 19, 23, and 38). When concentration is to be done at sand sizes coarser than those treated by froth flotation, rolls and rod mills are normally used (Sec. 2, Figs. 150 to 154, 159).

Crushing for sand-size rock products frequently involves a number of considerations not present in concentrating mills. Equiaxed particles are desired for concrete sands and gravels (see Sec. 3, Art. 41); rounded grains are wanted for some abrasives and jagged grains for others (Sec. 3, Art. 1); fines are waste in many cases (*e.g.*, producing roofing granules, chick-grits, burning lime, concrete sand; see Sec. 3); the prescribed maximum size differs for different rock products, or for the same product under different specifications, through a considerable range; and there is also a wide range in breaking resistance and abrasiveness. The machines used range from short-head cones, suitable for the hardest and toughest rocks, to tumbling mills with rubber-covered rods, and include also many special machines (see Sec. 6)

Screening, whether wet or dry, is almost invariably done by vibrating screens; washing, with or without scrubbing, is a common accompaniment.

Storage in the form of surge bins is customarily provided in all well-designed fine-crushing plants, in order to insure constant feed rates to both crushing machines and screens.

Control. Interlocking automatic control of some sort between the different parts of a crushing plant is almost essential to safe and economical operation. The best systems provide an electrical interlock on starting, so designed that the final conveyor is started first and that thereafter successively no machine or apparatus can be started until all of the machines that ultimately receive its load are running at operating speed. Similarly a stall or other shutdown of any machine automatically throws out all of the machines in the interlock ahead of it. Provision is ordinarily made, however, to permit independent operation of machines preceding bins of considerable capacity, despite that discharge from the bin is cut off. Failing some approximation to this type of control, flooding of crushers, conveyors, and other machines is an inescapable and expensive incident to crushing-plant operation.

Dust collection, in more or less elaborate form, is a part of every modern crushing plant, even though the dust may have no value. Direct legal prescription, or the incidence of workmen's insurance, or public and private liability legislation would force prevention of dust in any case, but economies in plant operation more than pay the cost of even elaborate installations, and recovery of values is an important item in some cases. See Sec. 20, Art. 11; Sec. 9, Arts. 2 to 9; and Sec. 2, Fig. 29.

Crushing stages. The number of crushing operations in series in any crushing plant is determined by the maximum sizes of plant feed and product, and the receiving ability and allowable working reduction ratios for the particular crushing machines used. The continued product $R_{w_1} R_{w_2} R_{w_3}$ must be less than or equal to the ratio of limiting sizes of feed and product. If this ratio can be attained by two machines with allowable working reduction ratios R_{w_1} and R_{w_2} respectively, two stages only are necessary, etc. Working ratios for jaw and gyratory crushers rarely exceed 5, and normally fall between 2.5 and 3; the standard-cone working ratio may run to 9 or 10 but is more often between 4 and 6; short-head cones range from 2 to 10 with the mean around 5, but this includes some closed-circuit work; rolls in closed-circuit work occasionally have working ratios of 10, but the mean value from table 24 is between 2 and 3. Single-roll crushers are not so directly limited in working ratio as the preceding machines, but practically, as determined by capacity considerations, they work through much the same reduction range as jaw and gyratory crushers. The hammer mill has no real structural limit on reduction ratio, but it also is limited practically on balance between power consumption and capacity, to a ratio of 6 (rarely 8). The limiting reduction ratios of rolls and gridless hammer mills may be increased materially by closing circuit on them with a screen; this is also possible with short-head cones, although in this case it involves building up circulating load to the point that the breaking zone is packed with material, and power consumption and maintenance costs are liable to marked increases over open-circuit performances.

Storage of crushing-plant product is variously designed, depending upon the type of plant. In concentrating mills the mill-storage bin is the link between the crushing plant and the concentrating plant. It has several functions: (*a*) It acts as a surge bin to deliver as a uniform 24-hr. flow to the mill the daily mine or quarry production, which usually comes to the crushing plant and is crushed in one or two shifts. (*b*) It serves as a distributor, if necessary, to a plurality of parallel grinding units. (*c*) It acts as a mixing device to average out differences in mineralogical character of feed as drawn from different mines or different parts of the same mine.

In cement plants the process storage has similar functions (see Sec. 3*A*).

In stone-crushing plants, storage of the crushed rock is for the purpose of equalizing flow between production and shipment. Consumption and production are, in many localities, seasonal; hence storage may need to be large. Size is an important quality of product; hence sizes must be separated in storage, but segregation according to size within any one storage lot must be prevented. Ground storage (Sec. 18, Art. 5) is common because of the large tonnages involved and the fact that exposure to weather is not harmful.

Flowsheets of crushing plants for ores have been analyzed in the treatment summaries for the various metals in Sec. 2, *q.v.* Those for rock products are less well standardized and study of specific plants, with due consideration of specifications for products, is safer than generalization (see Secs. 3 and 3*A*).

Arrangement of apparatus in a crushing plant depends to a certain extent on the topography available, but principally on a few prevailing structural requirements and operating characteristics. (1) The foundations for the crushing machines should be substantially vibrationless, which means that they must be massive and rest on solid ground. (2)

Continuous transport of lumps coarser than 6-in. and passage of such material through storage is troublesome, to say the least. (3) Crushing-machine parts are both large and heavy, and replacement of wearing parts and minor repairs are necessary with relative frequency; hence adequate provision must be made for handling parts from supply room to the machines and for doing the necessary dismantling and assembly at the machine.

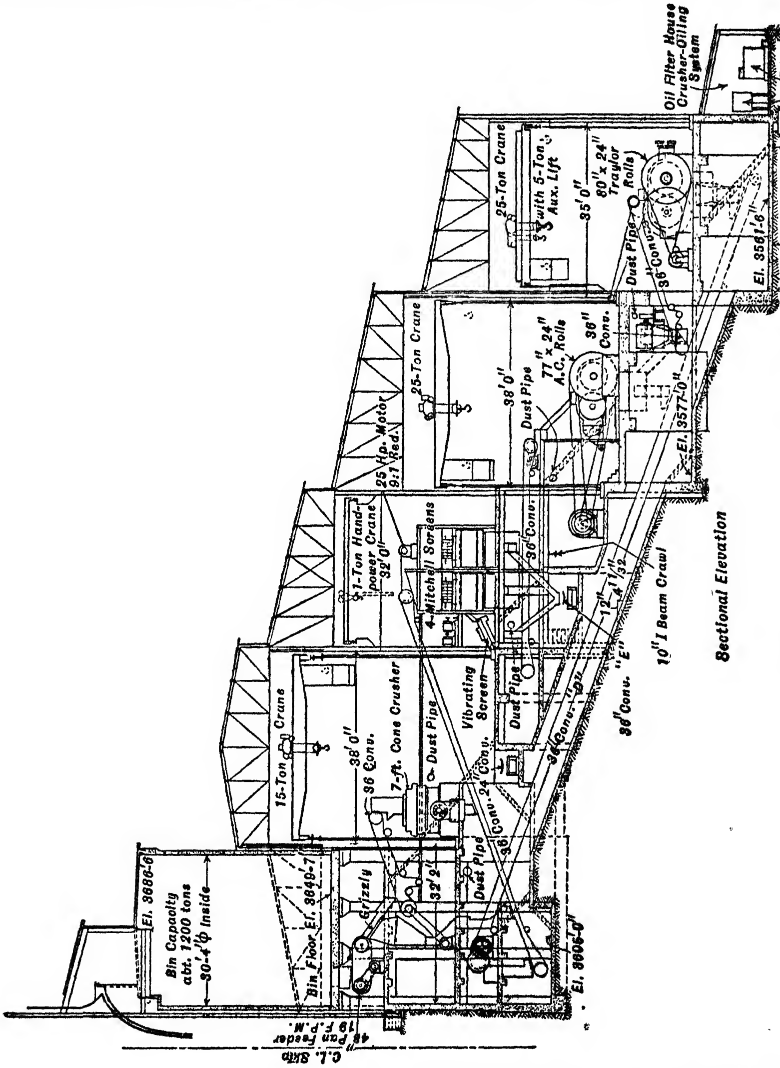

FIG. 67. Crushing plant, MIAMI COPPER CO.

(4) Constant attention is necessary only at the primary machine, but all of the heavy machinery should be at all times within the hearing and, better, within sight of an attendant. It follows, since an attendant is necessarily present at all times for the primary breaker, that if his duties at the primary machine will permit of the relatively inactive supervision demanded by the rest of the plant, it will make for operating economy to arrange the plant compactly. If, on the other hand, the plant is a large one, the machinery following the primary crusher requires more attention than can be given part-time by the primary-crusher attendant, and the plant may be spread out as much as desired, with each group of crushing machines, however, together with the accessory equipment, suffi-

ciently large to justify full-time attendance by at least one man. In such a case, since mill storage and the mill itself are frequently at a considerable distance from the point of crude delivery, it is usual to place the primary crusher at the point of crude delivery, and place the balance of the crushing plant between the primary and mill storage, with such horizontal distances intervening as will allow for necessary elevation on belt conveyors without back-tracking. Figs. 24, 26, and 27, Sec. 2, show one such arrangement. See also Sec. 3, Figs. 77 to 85. Fig. 67 shows a conveyor arrangement necessary in compact plants, or in any plant where crushing circuits are closed. Occasionally the primary crusher is placed underground; this is particularly advantageous when mining breaks the ore in large slabs,

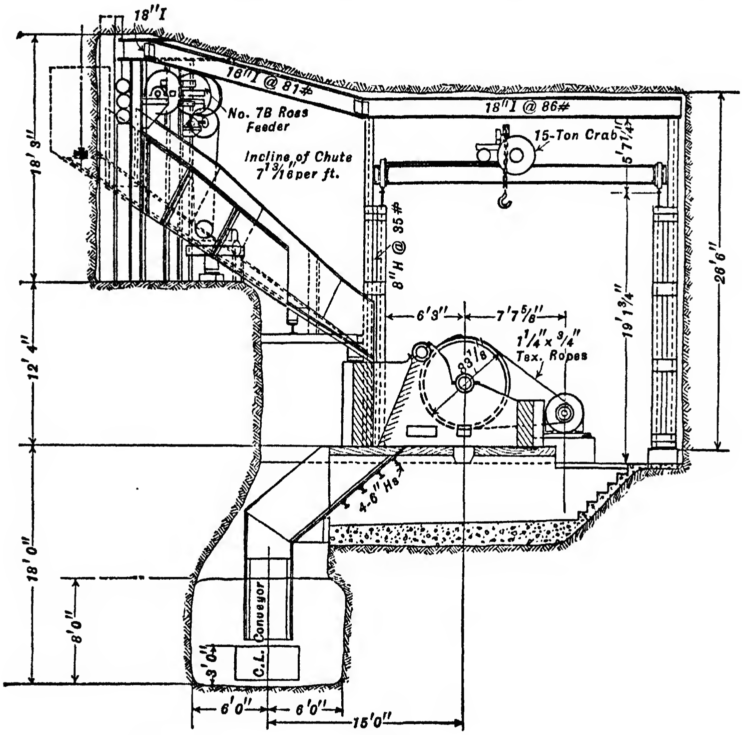

FIG. 68. Crusher station, 12th level, NORANDA MINES.

since these cause much trouble in loading skips. Underground crushers are usually of jaw type, because these sectionalize more readily than the gyratory. The arrangement shown in Fig. 68 is typical.

Lubrication. Judging by the range in consumption of lubricants reported in the several performance tables in this section, lubrication is a haphazard matter at many plants, and not impossibly inefficient at most. The basic aims of lubrication are simple; practice is largely empiricism. A LUBRICANT is a substance, usually a liquid, inserted between substantially contacting solid surfaces moving with respect to each other. It forces the surfaces apart, and substitutes its inner friction, *i.e.*, viscosity, for sliding friction between solid surfaces. It follows from its function that it must be able to penetrate, usually without application of pressure, between the surfaces; once there it must either remain or renew itself continuously, so as to maintain a film between the surfaces; and it must not corrode the surfaces that it is lubricating.

Penetration is not completely understood, but since it is invariably aided, in the case of close-fitting bearings under heavy pressures, by inclusion in the lubricant of small amounts of substances which are flotation collectors for the metals in contact, it is probable that it involves the same phenomenon of solubility wetting as occurs with oily collectors in flotation (Sec. 12, Art. 6). With crude, loose-fitting, microscopically rough bearings, penetration is largely capillarity. In either case, it is aided by low viscosity of the penetrant.

Maintenance of film in the rubbing zone is not well understood. Films that maintain themselves well under high pressures are said to have high FILM STRENGTH, but this is merely naming the phenomenon and not explaining it. High film strength is usually, but not always, associated with high viscosity and good penetrating ability. No sufficiently comprehensive correlations have been established between the chemical and physical properties of the lubricant and film strength to permit certain prediction; hence whether a lubricant has high film strength must be decided by trial in any particular case.

Viscosity of lubricants for crushing-plant machinery is important primarily from the standpoint of keeping the lubricant in the region to be lubricated. (With high-speed bearings operating under low pressures and with little power, it may be important from the standpoint of power consumption.) A lubricant with too low viscosity runs through and out of a bearing quickly and, unless provision is made for circulation, is lost. This is usually the explanation of high consumption, and, in flotation mills, of irregular work in the flotation plant, since much of the spilled lubricant appears, spasmodically, in the flotation cells.

Oil used for lubrication of all but the most unusual bearings is a petroleum fraction, its viscosity increasing, in general, with its boiling point. Many oils are, however, compounded with small amounts of animal or vegetable oil, or other organic compounds, in order to increase their penetration and film strength.

Grease is an oil that has been thickened by mixing with it finely dispersed solid soap, in much the same way that water is thickened to mud by intermixture with finely divided rock. The soaps are usually stearates, and the bases ordinarily soda or lime. Soda soaps make high-melting greases, which are, however, subject to disintegration by water, owing to solution of the soap. Lime soaps are used in soft greases; they are relatively resistant to water, but tend to separate at high temperatures. Both soaps stiffen the greases more or less in direct proportion to the soap content. The oil is, of course, the primary lubricant. Waste and other fibrous organic material serves much the same purpose as the crystalline soap structure in holding oil in place in some bearings. Both expedients are used to combat the tendency of the oil to run out of open or loose bearings as it loses viscosity with rise in temperature. Grease, however, has the added advantage of stiffening somewhat as it emerges from the bearing (and cools) and thus tends both to decrease further loss and to exclude dust and grit.

Filtering and cooling should be practiced on all oils that are circulated in crushing machines. It is almost impossible to seal grit out entirely, and the only way, therefore, to save the rubbing surfaces from acting as ultrafine grinders (with resultant wear and heat) is to filter the oil on each circuit. Cooling is not so essential except when the crusher is running continuously under heavy load, but since indirect heat exchange with water through a coil is simple and cheap, cooling after filtration is common.

Choice of a lubricant. The ultimate and, today, the only practical test for a satisfactory lubricant is a service trial. The lubricant should enable the bearing to run cool, it should not pit either of the rubbing surfaces, and it should not have an excessive cost either by way of consumption or price. If, additionally, it does not make for hard starting, that is desirable, but is, in general, relatively unimportant.

Rough correlations between certain physical properties, notably viscosity for oils, and so-called melting points for greases, and the behavior of the lubricants in certain general types of service are known to the sales engineers of the large oil companies. They usually know also the amount and kind of compounding dope that has been added, if any. On the basis of this information, and knowledge of performances in similar service elsewhere, they can ordinarily recommend a lubricant for any given crushing-plant service that will, at least, prevent burnt-out or rapidly pitted bearings. Thereafter determination of the best available lubricant for the service is a matter of trial. All of the large companies have substantially the same crude stocks available, can cut the same fractions, use fundamentally the same methods of refining and compounding, and produce, therefore, substantially the same products. They differ, consequently, as sources of supply, only in experience of the sales forces and in the price that is associated with a particular trade name. This generalization is less true of greases than of oils, since some special greases are made by processes that are secrets of particular grease compounders, but chemical and microscopic tests will normally decipher the secret in a short time, if it is worth while; whereupon the product is usually available from other sources.

Sales booklets discussing lubrication of different kinds of equipment are distributed by most of the large oil companies.

Hard-facing of all steels subject to abrasion in crushing plants is standard practice. There is a wide variety of patented alloys sold under different trade names, and having widely different properties of hardness, toughness, and ductility. Usually the principal component is iron, and chromium, manganese, and nickel are the usual alloying elements. The high-iron varieties are ordinarily tough and reasonably ductile, being thus resistant to shock, and have abrasion resistance about twice that of ordinary high-carbon steel. The low-iron alloys, consisting principally of chromium, cobalt, and tungsten, have high resistance to abrasion (3 to 10 times that of high-carbon steels) but are less shock-resistant than the high-iron types and differ greatly in this respect as between the different compositions available. Practice to date has favored the high-iron alloys for crusher parts; there has been some use of the low-iron mixtures for grizzlies, chute lips, and the like. Applica-

tion is by welding. If the under-surface volume to be replaced is large, it is first filled in to a large extent with manganese steel, and the hard-facing is then welded in on top.

The following applications are reported by a seller (*143 #6 J 66*): 125 lb. of rod used to build up a gyratory mantle at a cost of about 40% of a new mantle; little wear shown after a year of service. A mantle, 2 1/2 in. thick when new but worn thin, was built up with 90 lb. of rod in 25 hr. welding time at a cost slightly more than 25% of a new mantle; wear after 4 months (28,000 tons pyritic copper ore crushed) was 5/32 in. A large gyratory mantle from which 1,400 cu. in. had been worn was rebuilt with 250 lb. of manganese steel and hard-surfaced with 200 lb. of rod in 104 hr. Jaw plates and ball-mill liners have been reribbed in place, the latter operation involving welding on scrap steel and then hard-facing.

Operating logs. The crushing plant is more subject to delay than any other part of a milling operation. For this reason an operating log should be kept on the plant as a whole, with regular entries at reasonably frequent intervals (*e.g.*, hourly), showing essential tonnage rates at the entry times, the times of all shutdowns and start-ups, and operators' comments on causes of all variations from normal operation. Logs should also be kept for individual machines, on which are recorded the sources and nature of supplies; the dates, nature, and labor consumption in maintenance and repairs; and the amount of lost time chargeable to the machine. These are matters of recollection and guesswork in most small and many larger plants; the keeping of accurate records is frequently a hallmark of efficient operation. Forms should be kept simple, and be as brief as is consistent with recording essential information; they should be studied and digested by the supervising staff, and the fact of such consideration should be made known to the operators.

Cost of crushing and conveying ore of average hardness from steam-shovel size to <1-in. will range from 3 1/2 or 4¢ per ton in very large plants to more than double this figure in plants of 200 or 300-t.p.h. capacity; for hard rock add about 50%; for limestone, perhaps 25% may be deducted safely for the smaller plants, but it is questionable whether large plants will cut much below 3 1/2¢. Cost in a large plant for crushing from <1-in. to <10-m. will range from 4 1/2 to 6¢ per ton for average ore, including closed-circuit screening and the necessary conveying; in plants of medium size the range should be from 6 to 10¢ per ton; it may run to double these figures in small plants. Hard rock may well add 35 to 50% to the figures given; soft rock will not reduce the figures much, if at all.

Portable crushing plants are often used for small construction jobs when stone from stationary plants is not available without expensive haul. They range in elaborateness

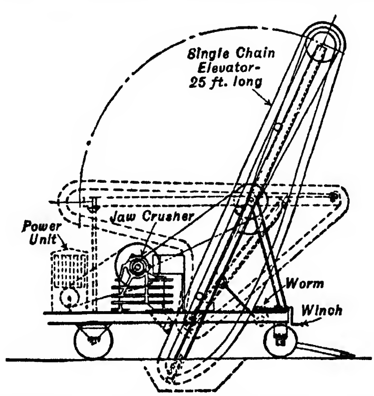

Fig. 69. Single-unit portable crushing plant

from a small crusher and drive unit mounted on a wheeled platform, to a combination consisting of primary and secondary crushing units, usually separately mounted, together with a feed conveyor, a connecting conveyor or elevator, screens, storage hoppers, and a loading elevator. The primary crusher is of jaw or gyratory type according to whether receiving capacity or production capacity predominates in desirability (see Art. 4); a secondary is almost invariably of gyratory type. Screens are normally of the simpler, low-slope, long-path vibrating type with one, two, or, rarely, three decks, mounted above the final crusher, and fed by elevator. Conveyors are usually separate units, driven from head or tail pulley as convenient, ordinarily from the crusher drive shaft. Elevators are driven at the head, usually by chain from a countershaft on the elevator frame, which is frequently

made collapsible. Drive is normally from a gasoline or Diesel-type engine, with V-belt, but steam engines mounted with boilers on a separate portable unit are not uncommon. Capacity ranges up to 15 to 45 cyd. of $1/2$-in. to 1 $1/2$-in. stone, depending upon the size of stone, for a 2-unit plant.

A simple jaw-crusher plant, without provision for feeding or sizing, but with collapsible elevator for truck delivery, is shown in Fig. 69. A two-crusher unit, mounted on one

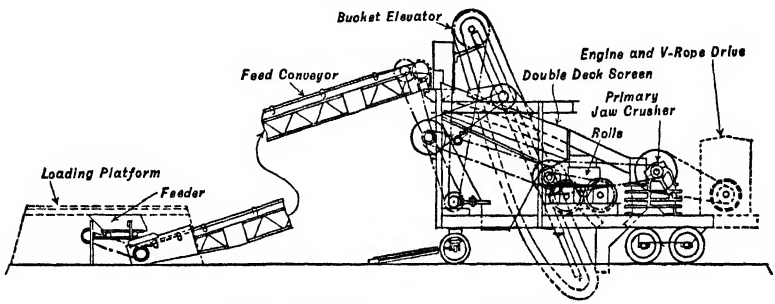

Fig. 70. Two-unit portable crushing plant.

portable base, with a double-deck screen which scalps the feed to the primary jaw crusher and closes circuit on the secondary crusher (in the form shown, rolls), is shown in Fig. 70. This outfit delivers one product only, *viz.*, undersize of the lower screen deck. This material would normally be picked up by a second conveyor or elevator and be delivered to a final screen located above a portable bin.

SECTION 5

WET GRINDING

1. INTRODUCTION

Grinding is powdering or pulverizing by pressure and abrasion. The essential element of all grinding apparatus is, therefore, a means for applying compression and shear to particles in such a way as to cause their rupture. Since fine powder is the desired product, it follows that in most cases the comminuting means must come close together in order to apply the necessary rupture forces. Hence one DEFINITION of a grinding machine is that it is a crushing machine in which the crushing elements touch except in so far as they are prevented from doing so by the material being broken (*Fahrenwald, RI 2989*). Grinding mills thus differ fundamentally from crushers (Sec. 4), in which contact of the crushing faces is prevented by the mechanism itself.

Grinding in some form or other is the only commercially practicable method of comminution available to produce material at maximum sizes of 20-m. or finer, and it is at least debatable whether it is not the economical method for production of 10-m. or even 6-m. maximum sizes (Art. 5). Limiting reduction ratio is usually large (8 to 25 : 1). On the other hand, there are unquestionably both a maximum feed size for efficient work and a maximum reduction ratio for a given type of grinding of a given maximum size of a given rock.

Definitions. Grinding is sometimes classified as COARSE GRINDING, denoting a product falling between, say, 6-m. and 20-m. maximum grain size; INTERMEDIATE GRINDING, say 28-m. maximum grain to 75% <200-m. (about 65-m. maximum); and FINE GRINDING, when the coarsest grain is 100-m. or finer. PRIMARY GRINDING is the first grinding operation to which a rock is subjected; SECONDARY and TERTIARY denote subsequent grinding stages. Grinding machines most frequently used are TUMBLING MILLS, comprising a rotating container partly filled with loose hard bodies free to move as the container revolves. Other types are ROLLER MILLS, in which heavy rolling bodies are constrained to travel a fixed circular path pressed against a track or tire; RUBBING MILLS, consisting of a heavy movable part or parts arranged to rub against a fixed surface; and STAMPS, in which a heavy mechanically actuated pestle strikes material on a fixed die in a mortar. Grinding is ordinarily continuous, but there is some batch operation, *e.g.*, barrel amalgamation and certain processing of nonmetallics to very fine sizes.

Purposes of grinding differ with the material being ground. In concentrating plants the primary purpose is severance sufficient to liberate the bulk of the valuable minerals from the gangue and, in many cases, from each other; secondarily it may be necessary to reduce the size of liberated valuable mineral sufficiently to effect differential movement in the subsequent concentration, *e.g.*, in flotation. In some nonmetallic beneficiation, grinding is practiced to satisfy market requirements, no question of separation being involved. In hydrometallurgical work, exposure of the valuable mineral to leach solution, rather than severance, is the sole purpose.

Liberation means severance of the mineral constituents of a rock. Gaudin (*PMD*) estimates, on theoretical grounds, that if a two-mineral rock in which the minerals occur

in equal-sized cubical grains, equally dispersed in equal volumetric abundance, were broken into cubical particles half the dimensions of the original grains, only one in eight (12.5%) of the resulting grains would be pure mineral, assuming no preferential breaking at the grain boundaries; breakage to $^1/_{32}$ of grain size would be required with such a rock to liberate 90%, and to $^1/_{512}$ to free substantially 100%. If the minerals are unequally abundant the same figures hold for the less abundant mineral, but the percentage of liberation of the more abundant is much larger; thus with a 10 : 1 volumetric ratio of more abundant to less abundant in the original rock, breakage to a particle size equal original grain size produces 50% liberation of the more abundant, and 90% is free at $^1/_4$ original grain size. With the less abundant comprising about 4% of the volume of the rock, corresponding to a fairly rich copper ore, liberation of more abundant is 80% when particle size equals grain size, and 92% at half-grain size.

Actually the adhesion at grain boundaries is usually less than cohesion across a surface through the grain itself; furthermore when a rock is ground to a given particle size, say that of the grain size of the less abundant mineral, 80 to 90% is finer than half-grain size, 70 to 80% is finer than quarter-grain size, and 60 to 70% finer than $^1/_{10}$-grain size. It follows that without any preferential grain-boundary cleavage, grinding a relatively rich ore to the predominating grain size of the valuable mineral will free a product in which at least 80% of the coarsest grains are free gangue, and well over 90% of all grains are free gangue, although only about 70% of all of the valuable grains would be free. Preferential boundary cleavage increases these percentages to such an extent in the usual ores as to justify the rule to grind to the prevailing grain size of the valuable mineral.

Gaudin (*ibid.*) gives photomicrographs of a number of typical mixed-sulphide grains from actual concentrates (Fig. 1). Item *a* is typical of a locked-middling grain in coarsely disseminated primary ores, and the *G* and *S* might equally well denote gangue and sulphide respectively. Items *b* and *c* are typical of secondary copper sulphides in which primary pyrite has been host for copper-bearing solutions. Particles like item *b*, in which the bulk of the particle is quartz, are also common in such ores. Item *c* is often found with galena the outer shell and pyrite or sphalerite internal. Items *d* and *e* are typical of complex primary sulphides, and of secondaries in which alteration has proceeded to the point of almost complete replacement of the pyrite host, it then comprising the internal phase. The silver-bearing gray-copper minerals also frequently thus occur as internal phase to other sulphides and to quartz.

It is to be noted that the requirements for liberation for leaching would be satisfied completely by items *a*, *b*, and *c* and in part by item *e*, but in no way by item *d*, if the mineral to be leached were the internal phase.

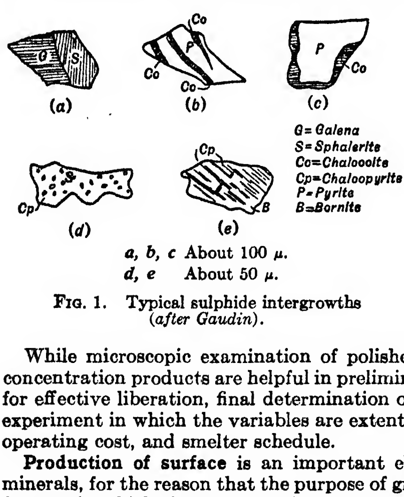

FIG. 1. Typical sulphide intergrowths (*after Gaudin*).

While microscopic examination of polished sections of original ore and of laboratory concentration products are helpful in preliminary estimates of the extent of grind necessary for effective liberation, final determination of the economic optimum is a matter of plant experiment in which the variables are extent of grind, mill recovery, grade of concentrate, operating cost, and smelter schedule.

Production of surface is an important element in the grinding of most nonmetallic minerals, for the reason that the purpose of grinding in such cases is to prepare the material for uses in which chemical reaction of some kind is involved.

Character of product is more important in concentrating plants than either high efficiency or low cost. An overground product, whether treated by gravity or flotation, will usually cost more in tailing loss than it is possible to save by efficient grinding operation. Overgrinding does no harm in cyanidation unless it results in preventable waste of power and steel. An incompletely liberated or exposed product usually results in high tailing and may at the same time produce low-grade concentrate.

Mechanism of fine comminution. The size characteristics of broken rock particles are determined, other things being equal, by the way in which the particle broken was loaded, and by the degree of hindrance offered to egress from the breaking zone. In general, shear loading (ABRASION) is more productive of fines than loading a particle as a short column; impact produces more fines than gradual loading; and the greater the hindrance to egress, the finer the product. Hence grinding machines are designed to strike the particles to be ground sudden, hard blows, and/or to cause them to be rubbed with considerable pressure against each other and against hard surfaces; also some device is always used to hinder escape of unground material from the grinding zone. The nature of the expedients used to

effect these ends determines the type of machine. Since the particles to be broken are relatively small, of highly varied size, and substantially infinite in number, it is not feasible to lead them through a restricted crushing zone, as in coarse and intermediate crushers, with the certainty that all will be reduced to some predetermined maximum thickness. Hence repetitive chance is called upon to effect presentation to the crushing surfaces. Two methods are employed. In tumbling mills the entering stream of pulp is broken up into a large number of small branches and is thus led relatively rapidly over a crushing surface of large extent. In roller and rubbing mills the crushing surface, on the other hand, is of relatively small area, and repetition is had either by repeated circulation or by tremendously slow travel. Hindrance to egress is effected by a screen or by a weir. In all cases the crushing surfaces alternately approach to and recede from each other; this motion is positively controlled and is substantially regular and uniform in the roller and rubbing mills, but less regular and definitely nonuniform in tumbling mills.

Capacity depends, in all types, upon the force exerted between the crushing surfaces and upon the proportion of time that the particles are in active crushing zones.

TUMBLING MILLS

Tumbling mills are used for grinding in substantially all concentrating and leaching plants and in many plants processing nonmetallic minerals. Operation is universally wet in the former group, but is frequently dry in the latter. Use of a sizing device to guard the product is usual, the exceptions being those cases in which the product is to be ground further (primary mills), and occasional remnants of old practice, *e.g.*, in some cement mills, where the circuit is guarded by prolongation of the mill shell.

Classification of tumbling mills. In the majority of tumbling mills the rotating container is a cylinder mounted with axis horizontal, and provided with openings through the heads for feed and discharge of material respectively. Differentiation is on the basis of tumbling bodies, shell proportions, and method of discharge. In ROD MILLS the tumbling bodies are steel rods; in BALL MILLS, cast-iron or steel balls; in PEBBLE MILLS, pebbles of hard rock or other nonmetallic material, *e.g.*, porcelain. The name BALL MILL usually further connotes a shell of which the length is not ordinarily more than twice the diameter. TUBE MILLS have the shell length two or more times the diameter; they may be loaded with either balls or pebbles or a mixture of the two. CONICAL MILLS have a cylindro-conical shell and utilize either ball or pebble loading.

Manufacturers of tumbling mills. Allis-Chalmers Mfg. Co., Chalmers & Williams, Denver Equipment Co., Eimco Corp., Hardinge Co., Hassel Eng'g Co., Joshua Hendy Iron Wks., Mine & Smelter Supply Co., Morse Bros. Machinery Co., Patterson Foundry & Machine Co., Straub Mfg. Co., Traylor Eng'g and Mfg. Co., Worthington Pump & Machinery Corp.

2. MECHANISM OF TUMBLING

Introduction. The tumbling mill has greater over-all variability than any other apparatus used in ore milling with the possible exception of the flotation machine. It varies not only in size, but in the proportions and the outer and inner conformations of the shell; the tumbling bodies differ in shape, size, in individual and total weights, and in hardness, throughout tremendous ranges; the motions of the tumbling media, determined by their shapes, by the conformations of the shell, and by its diameter and speed, differ not only in degree but in kind with changes in the controlling variables; the total time that the material to be ground is under action and the degree of continuity of that time are operating variables, as is also the state in which such particles are subjected to the mill action. Each and every one of these variables affects the result obtained on a given material, and change in material itself effects fundamental changes in such results. In consequence, analysis of the performance of a given mill under given conditions is difficult and debatable, while prediction, even by experienced and skilled workers, is largely a matter of hope. Fortunately, informed integration of averages of actual past operations will bracket the ordinary new situation sufficiently closely to insure a reasonable approximation to the desired result. In such an integration the designer will do well to avail himself of the services of the engineering staffs not only of the tumbling-mill manufacturers, but also of those of the sellers of the accessory equipment of the grinding circuit.

Motion of the tumbling bodies in a rotating shell was first identified experimentally by Haultain and Dyer (*25 CMI 651*). They took moving pictures of short rods with striped ends contained in a short glass-ended cylinder. The motion comprises two distinct vari-

eties, (1) rotation of the rods around their own axes lying parallel to the mill axis, and (2) CASCADING (rolling down the surface of the load) or CATARACTING (parabolic free fall above the mass). These motions of rods and the similar motions of balls have been confirmed by many later observers

Cataracting. Fig. 2 is an idealized representation of the action in a mill operating at a speed to cause cataracting. In the lower part of the mill balls are in irregular layers concentric with the mill shell. The layer in contact with the shell itself is moving at substantially the same rate as the shell; the rougher the mill lining the less the slip. Any ball in this layer, between lines *a–a* and *b–b*, is subject to two sets of forces, one applied at the point of contact with the mill shell, in a direction tangent to the shell and (in Fig. 2) counterclockwise; the other applied on the opposite side of the ball and oppositely directed. This pair of forces acting on any one ball constitutes a couple and, since the ball is constrained by contact with the shell and with its neighbors, it rotates around an axis perpendicular to the plane of the couple, *i.e.*, parallel to the mill axis. The balls in the adjacent layer are similarly acted upon and similarly rotate, and every ball in the zone between *a–a* and *b–b* has similar rotation under the action of similar couples. This motion of individual balls is shown in Fig. 3. The result is sliding of contacting surfaces across each other under pressures dependent upon their depth in the mass. Particles nipped and passed between are ground by abrasion.

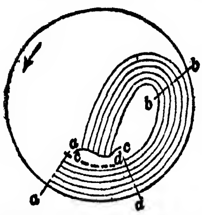

FIG. 2. Ball paths in cataracting.

In the zone from *b–b* to *a–a*, reckoning counterclockwise, in a mill operating at cataracting speeds, there is substantial free fall of balls out of contact with each other and no grinding or breaking action whatever. At the surface *c–c* there is crushing by impact between the falling balls and the balls below this surface, which are supported by the mill shell. In the zone *a–a*, *c–c*, *d–d* there is most intense and turbulent motion, appearing, in the moving pictures, to consist of violent tumbling in the region above the heavy dotted line and rapid shear of the mass along the dotted line with the portion of the balls below the line moving rapidly with the mill shell and those above appearing, as a mass, to be stationary, although each individual in this mass is in rapid movement with respect to its neighbors. Haultain and Dyer describe the zone *a–a*, *c–c*, *d–d* as the TOE; it is apparently the most active region in the mill and is probably the place where the most reduction of coarser particles is done.

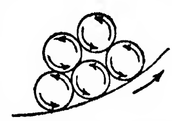

FIG. 3. Action of tumbling bodies in the layers adjacent to the shell of a mill.

Mathematical analysis. Davis (*61 A 250*) gives an exhaustive mathematical analysis of the action in a ball mill operated at cataracting speed. A summary of his conclusions follows:

Notation: (See Fig. 4) r = radius in ft., drawn to any particle p at the instant that its path changes from circular, under the impulse of the mill shell, to parabolic under the influence of its acquired momentum and gravity, or *vice versa*. r_1 = radius of mill drawn to the point where the outer layer of balls changes from circular to parabolic motion or *vice versa*. r_2 = radius to the point of motion change of the inner layer of that part of the charge which, at any given instant, is following a circular path. R = radius of gyration of charge near line aO. α = angle in degrees between vertical and radius r drawn to the point of change from circular to parabolic motion. α_1 = angle between vertical and the corresponding radius r_1. α_2 = angle between vertical and the corresponding radius r_2. αR = angle between vertical and R. β = angle between horizontal and the radius r drawn to the point of change from parabolic to circular motion. β_1 = angle between horizontal and corresponding radius r_1. β_2 = angle between horizontal and corresponding radius r_2. n = speed of mill in r.p.s. N = speed of mill in r.p.m. N_1 = critical speed of mill in r.p.m. V_b = velocity of particle relative to striking point. w = weight of any given portion of charge, *e.g.*, one ball, in lb. W = weight of entire charge in lb. P = fraction of mill volume occupied by charge (voids included). g = acceleration due to gravity = 32.2 ft. per sec. per sec. k = a constant for any given mill speed = $4\pi^2n^2/g$ = $1.226n^2$. K = a constant = r_2/r_1. H = height of charge in mill at rest, in ft. E = Kinetic energy in ft.-lb. T = time for a ball to complete one cycle, in sec. T_r = time for one rev. of mill, in sec. C_n = cycles of ball travel per rev. r_c = radius of circular arc aO along which change from circular to parabolic motion occurs. x, y, See Fig. 4.

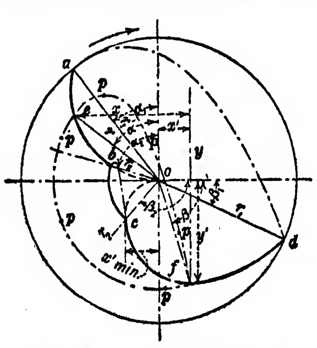

FIG. 4. Theoretical ball paths.

Equations:

$$\cos \alpha = kr = 1.226rn^2, \quad (1) \qquad r_c = \frac{0.408}{n^2}, \quad (2)$$

$$\cos \alpha_R = 0.867r_1n^2\sqrt{1+K^2}, \quad (3) \qquad N_1 = \frac{54.19}{\sqrt{r_1}}, \quad (4)$$

$$y = x\tan\alpha - \frac{0.613n^2x^2}{\cos^4\alpha}, \quad (5) \qquad \beta = 3\alpha - 90°, \quad (6)$$

$$V_b{}^2 = 16rg\cos\alpha\sin^4\alpha. \quad (7)$$

For the best theoretical efficiency

$$V_{b\,\text{max.}} = \frac{7.88}{n}, \quad (8) \qquad V_{b\,\text{min.}} = \sqrt{16Kr_1g\cos\alpha_2\sin^4\alpha_2}, \quad (9)$$

$$\alpha_R = 54°\,44', \quad (10) \qquad K = \sqrt{\frac{0.443}{r_1{}^2n^4}} - 1, \quad (11)$$

$$N = \frac{48.95}{\sqrt{r_1}\sqrt[4]{1+K^2}}, \quad (12) \qquad \cos\alpha = \frac{0.8165r}{r_1\sqrt{1+K^2}}, \quad (13)$$

$$\cos\alpha_1 = \frac{0.8165}{\sqrt{1+K^2}}, \quad (14) \qquad \cos\alpha_2 = K\cos\alpha_1, \quad (15)$$

$$C_n = \frac{T_r}{T} = 1.444 \text{ (considering all balls to have the same cycle as if their radius of revolution were the radius of gyration).} \quad (16)$$

$$K = -0.024 + 0.39\sqrt{7 - 10P} \text{ (very nearly)}, \quad (17)$$

$$\text{HP} = Wr_1^{3/2}\left[0.004467\frac{1-K^3}{(1+K^2)^{1/8}} - 0.0037\frac{1-K^5}{(1+K^2)^{3/8}} + 0.00088\frac{1-K^7}{(1+K^2)^{5/8}}\right] \quad (18)$$

$$r_2 = Kr_1 \quad (19)$$

Examples of application of Davis' equations. An 8×6-ft. cylindrical mill charged with 28,000 lb. of steel balls. Assuming 35% of voids in the ball charge, the weight per cu. ft. of charge is 325 lb. and the volume of the charge, 28,000/325 = 86 cu. ft. The interior volume of a 8×6-ft. mill is 301 cu. ft. (according to Davis. This figure is based on the assumption of 8×6-ft. inside. The actual internal volume of an 8×6-ft. mill is probably 20% less than this on account of the space occupied by the liners), hence the charge occupies 86/301 = 28.6% of volume = P. Then from Eq. 17, K = 0.770; from Eq. 12, the best speed = N = 21.8 r.p.m.; and from Eq. 18, HP = 153. (This is low for an 8×6-ft. mill.) If 8,000 to 10,000 lb. is added for the weight of the pulp and W is made the total load in mill = 36,000 to 38,000 lb., HP becomes 197 to 208, which is about correct (see Table 30). From Eq. 14, $\alpha_1 = 49°\,30'$ and from Eq. 15, $\alpha_2 = 60°\,20'$. From Eq. 19, r_2 = 3.05 ft. By Eq. 6, $\beta_1 = 58°\,30'$ and $\beta_2 = 91°$. Values of r for values of α between α_1 and α_2 may be obtained from Eq. 1 and for values of β between β_1 and β_2 from Eqs. 6 and 1. By plotting these values, curves *a–b* and *c–d* in Fig. 4 may be obtained. Then the concentric circular arcs represent the circular paths of the balls and the parabolas the free-moving paths. The value of r for the start and finish of any particle on its parabolic path is the same. The equation of the parabolic path of any given particle, taking its point of starting on the parabolic path as origin of co-ordinates, is given by Eq. 5. Thus the complete theoretical path of the ball charge can be plotted in a chart similar to Fig. 2.

Haultain and Dyer (*69 A 198*) question Davis' conclusions as to ball paths on the basis of their pictures, but Davis' discussion of their results confirms his original conclusions. Fig. 5 shows five different conditions of operation graphically summarized by Davis from the films. The dash lines in the figures are the theoretical paths. The lines carrying round black dots represent actual paths of individual balls as traced from the films. In Figs. 5*a* and 5*d* departure of the actual paths from the theoretical is greatest. In these operations balls and water only were present, and the discrepancy is due to slip between ball load and lining, amounting to 8 to 10%, resulting in failure to carry balls to their full theoretical height. This slip eliminated practically all free fall in Fig. 5*a*, and materially decreased the amount of free fall in Fig. 5*d*. But in Figs. 5*c* and 5*e* sand (corresponding to ore) was present, slip was practically zero, and the actual paths approximated the theoretical very closely.

Gow *et al.* (*87 A 51*) ran a 36×6-in. squirrel cage (screen ends) with ball charges ranging from 10 to 50% at various speeds without ore or water. With a 10% charge, slip was so high that there was neither cataracting nor centrifuging at any speed. At 20% load there was some cataracting at speeds near critical (Eq. 4) but no centrifuging at the critical; the cataracting balls fell on the toe. At 30% load a good toe formed: cataracting occurred in the higher speed range and the outer balls were thrown to

the breast above the toe; there was no centrifuging at critical speed. At 40% load the outer balls centrifuged at critical speed, which the authors interpreted to signify cessation of slip; the cataracting balls hit the toe up to 75% critical. At 50% load the trajectories of the balls were flatter than for smaller loads at given speeds, which was attributed to overcrowding. Trajectories at all speeds were broader than those derived by the Davis formula, which the authors asserted to be due to continued pushing of balls after they leave the shell by those behind, such pushing continuing to the top of the ball path. They offered the following formula, attributed to Dean and Kidd, as representing ball path from shell to apex, the origin of rectangular co-ordinates being taken at the point at which the ball leaves the shell:

$$y = \frac{2.3V^2}{g}\left[\log \frac{\cos\beta - \dfrac{57.3gx}{V^2}}{\cos\beta}\right]$$

in which V = constant velocity along curve in ft. per min. = peripheral velocity of mill or ball layer, β = slope of tangent to curve at point x,y in degrees (α, of Davis), and g = 32.2 ft. per sec. per sec.

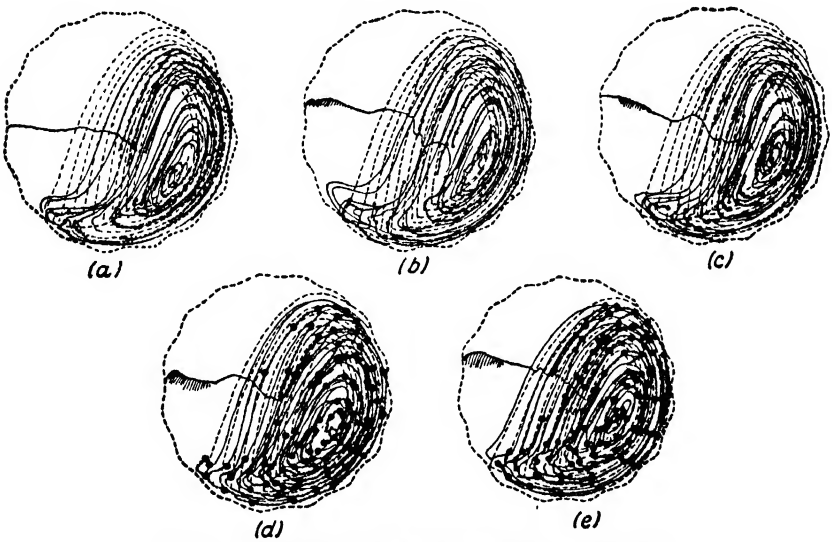

FIG. 5. Actual ball paths (*by Davis after Haultain and Dyer*).

Haultain and Dyer (*12 MMt 108*), by further moving pictures showing the differences in paths in squirrel-cage and glass-ended short mills, confirm the criticism by Davis in the discussion of the Gow *et al.* paper that the 1 1/4-balls used in the squirrel cage were keyed in, due to the short length and coarse screens (1-in. mesh), to such an extent that they carried beyond the normal departure points and were thus given greater-than-normal horizontal components of velocity. The weight of the evidence as to cataracting ball paths would seem to be in favor of the Davis analysis.

Cascading has not been thoroughly analyzed in the literature, despite that many tumbling mills nowadays run at substantially cascading speeds. The photographs of Gow *et al.* indicate, however, that in cascading, the branch *bb–cc* of the ball path in Fig. 2 simply collapses onto the upcoming layer, forming a small oval turbulent core in the upwardly concave part of the idealized void in the ball mass there pictured, over which the balls of the downcoming layer move as an avalanche. White (*87A 81*) states that with a 50% ball load the kinetic repose angles of the mill charge at various speeds are, approximately: 10% critical, 38°; 20%, 44°; 30%, 48°. The drawings of Gow *et al.* indicate rather higher values, with a definite drop in value for any speed with decreasing ball load (or smooth liner).

The toe persists in a cascading load. Observers report that while in cataracting the larger balls concentrate in and near the central void, in cascading they run out across the toe and tend to come up as the outer layer and thus form the surface of the avalanche.

Speed. The form of the inner surface of the liner, and the character of the pulp conjointly determine the character of the movement of the tumbling bodies in a mill of a given diameter. For a mill with a smooth liner, a single tumbling body should just cling throughout the revolution when the relationship between its distance from the mill axis and the mill speed are as given in Eq. 4, p. 05. This theoretical cling speed, taking r as the nominal

a Seasoned load; 3-in. renewals; forged steel; smooth liners, no lifters.
b Estimated from Table 5.

inside radius of the lining, is called the CRITICAL SPEED. In normal practice mills are run at 50 to 90% of this critical speed, depending upon the shape of tumbling body, volume of charge, shape of liner, and the type of action desired in the tumbling mass.

Speed *vs.* performance. Laboratory tests in a small ball mill (see Table 1) indicate a continuous increase in capacity with increase in speed over the range of 42 to 72% of critical for both very hard and relatively soft ores, with a further increase at 82% for the harder ore. Efficiency, on the other hand, shows a somewhat indefinite peak in the range between 40 and 50% of critical. There is no break in capacity marking the change from cascading to cataracting which, judging from the photographs presented, took place between 52 and 62% of critical. This is, however, the range in which efficiency began to drop; more for dolomite than for chert. The change is accompanied by a distinct swelling or loosening of the charge, principally in the down-going stream.

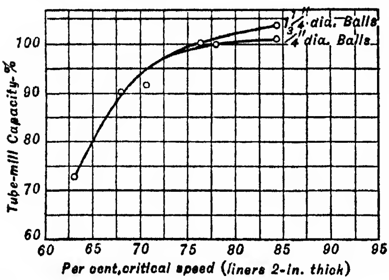

FIG. 6. Speed *vs.* capacity in a 5×16-ft. tube mill at LAKE SHORE.

Results of speed tests on a 5×16-ft. tube mill at LAKE SHORE (*LSS*) are given in Fig. 6. It is to be noted that the small gain in capacity with 3/4-in. balls in going from 77.6% of critical (27.5 r.p.m.) to 84.7% of critical (30 r.p.m.) was accompanied by an increase of 10% in power consumption. At HOLLINGER it was early decided on the basis of plant test work that 80% of critical was the best speed for a 7×6-ft. primary ball mill and for 6×16-ft. and 4×16-ft. tube mills. Table 2 presents data on later tests on a 6 1/2×7 1/4-ft. ball mill in which it is indicated (tests 2 and 5) that 81% speed is about 10 to 15% superior to 91% critical in efficiency while as between 81 and 72% (tests 4 and 7), the capacity at the higher speed is about 10% higher and the power increase slightly less, so that again there is a slightly better efficiency shown at the 81% speed.

Recommended speeds. MINE AND SMELTER SUPPLY CO. (*40 CIMM 328; PC*) recommend 75 to 78% of critical for low-level ball mills operating with wave liners. Johnson (*ibid.*) points out that 85% of critical is maximum for feeder-tip speed; above this feeders will not load properly, and at this speed there is considerable splash in the feed box. ALLIS-CHALMERS (*F. C. Bond, PC*) recommend the equation $N_o = 57 - 40 \log D$, where N_o is best operating speed and D is internal diam. of mill in ft. See also tables of manufacturer's data, Art. 7 to 11. Chenhall (*6 CIE*) states that in Cornwall mills the formula $N_B = K/\sqrt{d}$ is used, where N_B = best r.p.m., d = internal diam., in.; and K is 200 for a pebble charge with smooth liner and 183 for a ribbed liner, and 217 and 198 respectively for a ball charge. Thompson (M. & S. S. Co., *PC*) states that a peripheral speed of 300 to 330 f.p.m. appears to give the best rod action.

Except in highly competitive sales the manufacturer recommends speeds that are below those giving maximum capacity; the customer then has relatively low steel consumption, and when the almost inevitable demand for increased capacity arises can be told to increase speed and gain the capacity without loss in tons per hp-hr.

At FALCONBRIDGE NICKEL (HARDINGE CO., *PC*) an 8-ft. × 36-in. conical ball mill with wedge-bar liners and ball charge of about 16 tons was operated in closed circuit at 19.05, 21.3, and 22.0 r.p.m., corresponding to 68.3, 76.4, and 79.0% of critical, respectively. Corresponding power consumptions were 142, 148, and 160 hp. Capacities on <1/4-in. feed to 10% >48-m. product were 290, 310, and 335 tons per 24 hr., respectively, and the corresponding tons per hp-hr. were 0.085, 0.087, and 0.087. At KERR ADDISON (HARDINGE CO., *PC*) a 10-ft.×72-in. conical ball mill with wedge-bar liner and 38-ton load was operated at 19.8 and 21.8 r.p.m. (80 and 88% critical) in closed circuit with a 12×25 1/2-ft. Dorr DFX classifier. Power drafts were 462 and 492 hp. Capacities on hard, siliceous ore were 750 and 730 tons respectively reducing <3/4-in. feed to a nominal 48 *mog*, but the >65-m. was only 7.2% for the slower mill as against 10.1% for the faster, and the <200-m. quantities were 61.2% and 54.1% in the same order. Thus the slower mill consumed 14.8 hp-hr. per ton of feed and 27.8 hp-hr. per ton of <200-m. produced as against 16.2 and 34.5 hp-hr. respectively for the faster mill. The FALCONBRIDGE figures show a pick-up of 15% in capacity with no appreciable sacrifice of efficiency by increasing speed up to 79% of critical; the KERR ADDISON figures, on the other hand, indicate that the optimum speed has been passed. At AJO (*C. F. Thompson, PC*) increase in speed of 7-ft. rod mills from 17 to 23.1 r.p.m. increased capacity 43.4% with 9.7% decrease in hp-hr. per ton. (Conversion to a ball charge gave a further increase in capacity, maintaining the same power consumption per ton ground.)

Table 3 summarizes practice as to speed for 172 installations reported over a period of 20 yr. The clustering of ball-mill speeds above 70% of critical speed and of those for rod mills in the range from 50 to 60% is marked. If it is assumed, as is asserted by Gow *et al.*, that their 2×2-ft. laboratory-mill results are an accurate reflection of the performances of large mills, ball-mill practice is, definitely, to sacrifice efficiency to capacity. Rod-mill practice, on the other hand, is predominantly in the cascading range. Recent work (Art. 7), however, has shown that rod mills can be run at speeds above the nominal critical without tangling the rods or hammering out the linings, and that at such speeds they are

serious competitors of rolls in preparation of fine ball-mill feed. Pebble-mill speeds are, in general, higher than those of ball mills.

Table 3. Speeds of tumbling mills in practice

b All but one of these of small diameter (3- and 4-ft.) and early installations.

Low ball-mill speeds are sometimes employed as an economy when full mill capacity cannot be utilized. Coghill and deVaney assert (*CEG*) that ball action is better than rod action at very low speeds

Very high ball-mill speeds, which cause the outer layers of the load to be thrown clear of the toe and against the down-going breast of the mill, waste the impact of the bodies thus thrown and cause excessive consumption of steel. It is the consensus of operators that high speed increases capacity in coarse grinding and that lower speeds are better for fine grinding, but the statistical showing of Table 2 does not reflect action on this opinion. One large manufacturer recommended a drop in speed of approximately 10% about 1930 (*87 A 75*).

Variable speed to suit tonnages available and change in mill diam. with liner wear is definitely indicated. On the other hand, the only method presently available for speed variation is to use a d.-c. motor. This is not economical.

Particle loading. It follows from the discussion of tumbling action (p. 03) that at all operating speeds the particles in the interstices of the upcoming grinding media will be subjected to a rubbing pinch somewhat analogous to that in a set of rolls running with only one belt. At cataracting speeds the work done by the downcoming media is hammering against the balls of the toe and/or against the downcoming breast of the mill, plus a contribution to avalanche action (p. 10) in the toe. At cascading speeds the work of the downcoming stream is all avalanche action.

Rubbing, to be effective, requires that the particle be held relatively stationary with respect to the rubbing surface, *i.e.*, it must be nipped. The requisite angle of nip is the same as that for rolls (Sec. 4, Art. 8). Hence, on the face of the matter, there should be some relationship between diameter of tumbling body and particle to be broken. But the tumbling bodies are not constrained to the extent that rolls are; rather they can and do move apart to an extent dependent upon the superincumbent pressure, the size of the interstitial rock particles, and the resistance of these to breaking. Hence nip-angle calculations as a basis for determination of proper size of medium have no significance except as to the smaller rock particles, which have insufficient strength to withstand the pressures available (see Art. 3).

Hammering, or impact loading, generates stresses which, because of suddenness, are much larger than would be expected from the weight of the falling body (Sec. 4, Art. 9). This action is depended upon for crushing the larger rock particles. Its effectiveness, so far as an individual blow is concerned, increases with the inertia of the body struck. Hence a rock particle struck by a ball in the air suffers but little internal stress; one resting on or in a mass of pulp suffers but little more; but those which are backed by the media in the toe or by the shell become more or less fully loaded according to their ability to adjust position to the supporting and loading surfaces.

Utilization of hammering is aided in a mill operating at cataracting speeds by the fact that such action loosens and swells the load sufficiently to permit the larger bodies to work to the surface (see Sec. 11, Art. 15). Gow *et al.* report concentration of the large balls in the turbulent core at the surface of the upcoming stream, and increasing penetration of fine sand to the shell. Concomitant concentration of coarse rock at the surface of the tumbling load has been commented on by other observers.

Hence the same operating change that produces cataracting of the tumbling bodies, *viz.*, increase in speed, also serves to concentrate the larger particles at the surface of the toe, where they are struck while effectively backed.

Avalanche loading is a combination of rubbing and hammering, *i.e.*, both occur. The cascading bodies in each layer of the downcoming stream are retarded at their lower surfaces because of the slower down-slope flow of the underlying layer, which, in turn, is due to the drag transmitted from the upper surface of the upcoming stream. Conversely, the upper surfaces of all but the upper layer of downcoming bodies is subject to an accelerating force from the overlying layer. The result is a couple tending to cause rotation of the body around a more or less horizontal axis. Any differential motion between touching bodies thus engendered causes rubbing.

At the same time the bodies in the same layer are intermittently in and out of contact as they roll over the irregular surface of the underlying layer. As they make contact they exert impact stresses on intervening rock particles of a magnitude dependent upon the downsurging individual mass and the relative velocities of the striking and struck bodies. Data are not available for quantification of the forces, but their relative ineffectiveness as compared with free-falling bodies may be judged from the fact that a given load cascading will not reduce coarse feed particles as rapidly as the same load cataracting. If the same feed rate is maintained, the coarser particles in the discharge from the cascading mill come out rounded, indicating insufficient loading to break across them.

Cascading *vs.* cataracting. Gow *et al.* (*112 A 24*) ran parallel laboratory tests on <3-m. dolomite at 32% and 72% of critical speed at feed rates that were equal in tons per hp-hr. Cataracting was prominent at the higher speed and absent at the lower. Distribution curves (Sec. 19, Art. 19) on the products show more complete natural-grain release at 28~35-m. and a steeper slope (coarser) fine grind at the higher speed despite the percentages of <200-m. being substantially the same in both cases (17.6% at 32% critical and 17.0% at 72%). The peaks of the distribution curves were of the same elevation and occurred at 20-m. (36% of the *mog*), but the coarser material was slightly finer at the higher speed. Power draft at the cataracting speed was higher, feed rate was higher, and time per pass lower. The conclusion is, therefore, that hammering breaks down the coarser material more rapidly than rubbing, frees natural grains more readily, and does not produce as much very fine material with the same expenditure of power.

3. SHAPE OF MILL

The mill barrel comprises the shell and liners. The shapes that have withstood the test of time are cylindrical and cylindro-conical. Diameters of commercial mills range from 3 ft. to 10 ft. and yet larger sizes are in prospect. Lengths have ranged from 2 ft. to 24 ft. The ratio of diameter to length ranges from 0.23 to 1.5. The inner surface ranges from smooth to various degrees and forms of roughness. The relative diameters of inlet and outlet openings, taken with mill lengths, determine the mean slopes on which pulp flows through the barrel, ranging from a small fraction of an inch to several inches per foot. All of these structural differences produce corresponding differences in mill operation and performance.

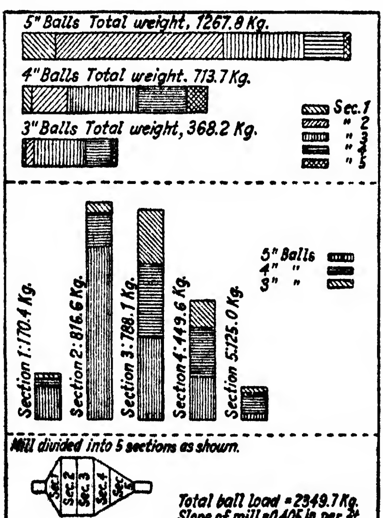

FIG. 7. Distribution of balls in a conical ball mill.

The barrel supports, confines, guides, and imparts driving force to the tumbling load. Consequently its shape, together with the mill speed, has a major effect in determining the paths both of the individual tumbling bodies and of the mass thereof, and of the pulp; its diameter taken with the extent to which it is loaded determines maximum and average crushing pressures in the tumbling load; and its volume taken with the feed rate and the comparative levels of its feed and outlet lips determines the time per pass that the average particle is subjected to grinding action.

Paths of tumbling bodies, in so far as they are determined by the barrel, are such that the center point of any given tumbling body in the usual cylindrical barrel travels in a roughly plane surface perpendicular to the mill axis when the mill is run at cascading speeds (Art. 2). Particles of rock follow similar paths except as they are forced toward the outlet by difference in head of pulp and by the excess of baffling effect of the higher head-end closure. But in small models of cylindrical mills run without pulp at cataracting speeds, the ball load heaps up against the ends and there is marked concentration of the larger balls there. It is asserted by H. Hardinge (*PC*) that similar segregation has been observed on shutdown in high-speed operating mills.

In the conical mill with standard cones (Art. 7) one effect of the shape of the discharge-end cone is to guide the downcoming stream toward the base of the cone. The larger balls (rods are not used in

typical conical barrels) and coarser rock both tend to ride the surface of the load in the discharge cone because this part of the shell is below cataracting speed whether the cylindrical portion is or not. Since the surface layer is least confined, the result is that large balls are concentrated in the cylindrical section and coarse pulp tends to be returned to the coarse-ball zone. Size segregation of the crushing bodies is not sharp, but there is distinct concentration of the larger sizes at the longest diameter and *vice versa*, as is visible in a model, is shown for a working mill by Fig. 7, and is confirmed by the fact (*124 P 209*) that in changing from a 2-in. to a 4-in. ball load, charging 8 tons of 4-in. balls forced out an equal tonnage of the smallest sizes. There is also marked heaping up of the load in the cylindrical section in a model with a relatively short cylinder. This heaping increases at cataracting speeds.

The correlation between heaping and segregation in the conical mill, taken with the well-established (and mechanically reasonable) tendency for the charge to heap against the ends in cylindrical mills, would seem to support the Hardinge contention that there is segregation of large balls toward the ends of cylindrical mills, and to indicate further that this segregation will be greater the rougher the end sections.

Fine sand, which penetrates the load to the shell, tends, in a conical mill, to be accelerated toward the discharge lip on the rising side of the discharge-end cone by the lifting effect of the grooves at the liner joints, and by liner ribbing located along elements of the conical surface.

Diameter of barrel determines pressures in the tumbling load and affects impact magnitude in cataracting. Pressures in the tumbling load may be estimated very roughly along the lines indicated in Fig. 8.

In a static ball load averaging 300 lb. per cu. ft. of over-all volume (Art. 6), the mean pressure at any depth is slightly more than 2 lb. per sq. in. per ft. of depth. Maximum mean gravitational pressure in a load in dynamic equilibrium in the position shown in Fig. 8 would be against the shell under vector A, since this represents the maximum depth through which there is continuous ball-to-ball contact. The length of this chord is roughly three-quarters of mill diameter. Pressure is concentrated owing to the shape of the tumbling media. Assuming balls of one size, and a mean of cubical and hexagonal packing, the number of contacts per sq. ft. against the shell is approximately $157/d^2$, where d = diameter of ball in inches. Contact area per ball varies according to diameter and rock-particle size. Taking Bond's formula for contact area (Art. 6), and assuming 2-in. balls in a 6-ft. mill running at maximum cascading speed (dynamic repose angle about 60°), the number of contacts per sq. ft. against the shell would be about 40; the head would be 4.5 ft.; hence the mean pressure per sq. ft. would be 1,350 lb. or 34 lb. per contact. With 5.9 sq. mm. contact area for a 2-in. ball this makes ball-to-shell pressure of the general order of 3,700 lb. per sq. in. If this is doubled for shock, which seems justifiable, and the fact that even further concentration of load occurs by reason of the particulate and jagged character of the intervening rock particles is considered, the amazing thing is not that so much rock is crushed but that so much passes through without crushing. This is due, of course, to a number of facts. Balls in the load average at least three points of support; the mean head in the load (roughly half the average of A and B, Fig. 8) is much less than half of A; material between balls cushions shock; coarser particles fail to nip; and much of the finer material travels a considerably longitudinal distance between presentations to a grinding contact.

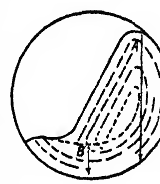

FIG. 8. Pressures in a cascading load.

Impact magnitude in cataracting is proportional to mv^2, where m is the mass of a falling ball and v its gravitational velocity. The latter factor is, of course, dependent on mill diameter. Practice tends to proportion mill diameter to maximum feed size, all other things being equal.

Length of barrel. Modern practice is to make the ratio of length to diameter from 1.33 to 3.0 for rod mills, the lower ratios corresponding to the smaller mills; for ball mills taking coarse feeds (>1/2-in. max.), the ratio ranges from 0.7 to 1.0; for primary ball mills taking feeds <1/2-in. maximum, ratios range from 1.0 to 2; for tube mills with ball charges the usual range is 2.5 to 3.3; and for tube mills with pebbles or with composite charges the range is normally 3.8 to 4.5.

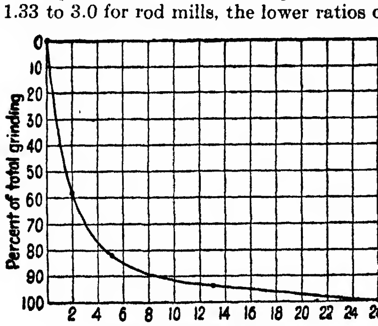

FIG. 9. Amount of grinding at different points in a 6×22-ft. tube mill, dry-grinding talc.

The reasons underlying these different proportions are various. Rod mills are made long in proportion to diameter in order to prevent the rods from becoming crossed, but Coghill and deVaney (*CEG*) assert that a 6×4-ft. mill with a rod load worked without rod tangling. Ball mills taking coarse feeds are made of large diameter to insure heavy impacts and high in-load pressures, and length is kept down in order to obtain the steep pulp gradient necessary with coarse material to minimize time per pass and permit large circulating loads. With finer feeds it is possible to maintain rapid flow with a lower pulp gradient, and since with a given mill diameter capacity is nearly proportional to length while power consumption does not increase quite

so rapidly, the longer mill is preferred for economy, if the capacity can be utilized, still maintaining the large diameter. Ball-tube mills are made long to gain time-factor while keeping down diameter to save power and liner wear. Pebble-tube mills require even longer time-factors because of low specific gravity of the tumbling media; diameter must be kept down in order to prevent pebble breakage.

A long mill which is underloaded may complete 85% or more of its total grind per pass in a length equal to its diameter (see Fig. 9). The remainder of the mill is then wasting power and, if preparing for concentration, may do harm to recovery and grade of concentrate by overgrinding. Even on a hard ore, wet-grinding with a pebble load, substantially 80% of total reduction to a normal flotation size is completed in the first half of the mill (see Table 4).

Table 4. Rate of grinding in 5½ × 22-ft. Rand tube mill (*After Dowling, RMP*)

Location of sample	Sizing test, % weight			Grinding, % of total reduction, effected	
	+60	+90	−90	+60	−90
Feed	73	20	7	0	0
4 ft. from feed end	46	29	25	45.8	36.0
11 ft. from feed end	26	30	44	79.7	74.0
18 ft. from feed end	19	34	47	91.5	80.0
Discharge	14	29	57	100	100

Change in length is a good way to vary capacity. Thus at ANDES 9×7-ft. mills were increased to 9-ft. length by flanging on additional cylinder. Increase in capacity was roughly proportionate to increase in effective volume (about 25%). Table 2 shows the effect of decreasing capacity by installing a grate at a distance back from the discharge end. For details of such an installation see Fig. 55. At SYLVANITE (*41 CIMM 283*) a 7-ft. Marcy mill was arranged for installation of the grate at either 8-ft. or 10-ft. length. The mill-volume difference was 24.5%; power difference was 21.6% (240 and 292 hp.).

Volume of mill barrel is important principally for its effect on the time of passage of pulp through the mill. The effective volume is roughly that between the shell and a plane inclined in the direction of the mill axis and extending from the bottom of the feed inlet to the bottom of the outlet annulus, diminished by the volume of tumbling media within this zone when the mill is at rest. (See also Art. 16.) The volume of pulp fed per minute divided into this effective volume approximates the TIME PER PASS in minutes.

The maximum rate at which pulp can be flowed through the mill depends upon the pulp consistency and the difference in elevation between inlet and outlet lips. No figures for estimate are known; the question must be solved by trial, if it becomes important. On the other hand, thin pulps may be so fluid that the pulp surface slumps well below the above-mentioned plane, in which case the effective volume decreases, time per pass decreases, wear of medium increases, and grinding usually falls off.

Large mills have a smaller ratio of shell weight to tumbling charge than small mills; therefore dead-load power (see Art. 15) is a smaller proportion of total power. Since the grinding work per unit of live-load power is constant within limits (see Art. 14), the larger mill is the more efficient. Its first cost per unit of capacity is also less, and the capacity per square foot of mill floor space higher.

At CIA. ASARCO (HARDINGE Co., *PC*) an 8-ft.×36-in. conical mill with 15-ton ball load running at 76% of nominal critical speed reduced 286 tons per 24 hr. of <3/8-in. feed to 48 *mog* (60.9% <200-m.) with 460% circulating load, drawing 13.4 hp-hr. per ton of new feed. On the same material a 10-ft. ×48-in. mill with 30-ton load, operating at 68% of nominal critical, handled 582 tons per 24 hr. to the same *mog* (61.4% <200-m.), with 300% circulating load and a power expenditure of 11.6 hp-hr. per ton. At CONSOLIDATED M. & S. the 10-ft. conical mill ground 15% more tons per hp-hr. than the 8-ft. through the same size range, and at ANACONDA a 20% advantage of 10-ft. over 8-ft. was indicated (Penick, *87 A 75*). Johnson (MINE & SMELTER SUPPLY Co., *112 A 86*) asserted that if INSPIRATION, in 1916, had installed the then prevailing 6×4 1/2-ft. Marcy mill instead of the 8×6-ft. which was installed, 100 of the smaller mills would have been required instead of the 40 large, 12,000 motor hp. would have been needed instead of 10,000, and the requirement for grinding-mill floor space would have been 13,000 sq. ft. instead of 8,000. Maxson (ALLIS-CHALMERS Co., *112 A 86*) concurred in the assertion that the large mills are more efficient.

On the other hand, Gow *et al.*, on the basis of laboratory tests, conclude that while large mills will grind more than small per unit of volume, they are not more efficient in production of useful new surface (Sec. 19, Art. 19). Coghill and deVaney (*CEG*) conclude, from comparison of performances of a 19×36-in. laboratory mill and a 6×4-ft. plant mill on the same feed and making substantially identical products, that the tons per net hp. are the same irrespective of mill size. Parsons (*60 CMJ 693*) apparently reads Davis' experiments (*61 A 254*) with stage crushing to prove that two small mills are more efficient than one large for the same tonnage. This reading would not seem to be justified by the text. Parsons asserts that tests at CONS. M. & S. confirm the greater utility of the smaller mill. The entire trend of recent practice is, however, toward the use of large units.

Height of discharge in relation to the elevation of the inlet opening, taken in connection with the length of barrel, determines the mean slope of the pulp surface and consequently the mean rate of flow of pulp through the mill. It also determines the maximum depth of any possible liquid body of pulp in the mill.

It is general experience that when running at cataracting speeds the presence of liquid pulp above the toe decreases reduction of the coarser feed particles, this decrease being the more serious the greater the pulp density. When feed is fine enough to be ground effectively without cataracting impacts, the effect of a pool above the toe is not so serious unless the ball load is far below normal (Art. 4).

Tests at LAKE SHORE (*LSS*) showing the effect on circuit capacity of change in height of discharge are summarized in Fig. 10. The reduction was effected by placing grates a few inches in from the discharge-end heads and providing lifters to elevate discharged pulp to the trunnion. In each case also, the change-over was accompanied by an increase in ball load from 45 to 50% of mill volume.

Legend, Fig. 10:

C1. Circuit 1, flowsheet as follows:

1. 2 @ 7×6-ft. ball mills, 24 r.p.m., 4-in. balls.
2. 2 @ 4×18 1/3-ft. rake classifiers.
3. 1 @ 16-ft. bowl-rake classifier.
4. 1 @ 6×16-ft. ball mill, 25 r.p.m., 1 1/4-in. balls.
5. 1 @ 16-ft. and 1 @ 24-ft. bowl-rake classifier in parallel.
6. 3 @ 5×16-ft. ball mills in parallel, 30 r.p.m., 3/4-in. balls.
A. All mills.
H. High-discharge, 13- to 15-in. I. D. trunnions.
L. Low-discharge, grate openings to shell, spiral-scoop discharge lifters.
P. 6×16-ft. mills only.

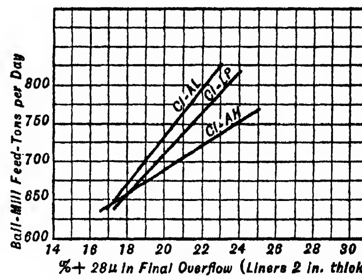

FIG. 10. Effect of height of discharge in ball-mill circuits at LAKE SHORE.

Independent tests (Art. 6) proved this increase to account for 80% of the capacity increase. Hence of the 8.3% increase in circuit capacity with a 24% >28-μ product accompanying the change in the 6×16-ft. primary tube mill, only 1.7% was directly attributable to the change in the primary mill. By a complicated method (see the original paper *43 CIMM 299*), the total improvement in performance of the 6×16-ft. mill was reckoned to vary from substantially zero at a grind to 18% >28-μ to 35% at 24% >28-μ, from which the improvement due to the change in pulp gradient alone ranges from 0 to 7% over the same tonnage range. About half of this amount of benefit was further gained by a subsequent change-over to grates in the 5×16-ft. mills.

Power increase on the change-over at LAKE SHORE was proportional to the capacity change. Of the increase of 22 hp. for the change in both the 5- and 6-ft. mills only 4 hp. was attributable to the drop in level itself. This was only about 2% of the total power draft.

Results of a similar change in the primary ball mills at HOLLINGER are shown in Table 5. The improvement from high discharge to full-grate discharge was 28% in tonnage to an insubstantially finer grind; the improvement in production per unit of power was much less, 7.7% in tons per hp-hr. to the same *mog*, 5.5% in tons <200-m. produced per hp-hr., and 6% in new surface produced per hp-hr. (Bond method, Sec. 19, Art. 19).

Parallel operation of 8-ft.×60-in. conical mills at UCHI GOLD MINES (*PC*), one with a low-level grate (Fig. 47), the other without grate but with a high-level discharge spout, both mills taking 1-in. feed and making classifier overflow containing 70% <200-m. showed that the grate-mill capacity was 14.5 t.p.h., while the capacity of the high-discharge mill was 13.8 t.p.h. Corresponding power drafts were 290 and 263 hp., so that tons per hp-hr. were 0.050 and 0.052, respectively.

High-level *vs.* low-level mills. The battle between the proponents of these two methods of operation is far from decided. The LAKE SHORE data (above) involve too much translation by the writers to be convincing by themselves. The HOLLINGER data (Table 5) indicate a real advantage in capacity for low-level operation with relatively coarse feed (<3/8-in.), but no marked difference in efficiency. Tests at INTERNATIONAL NICKEL (*32[1] Bul CIMM 269*) showed that installation of a low-level grate increased capacity and power consumption linearly. SYLVANITE (*32[1] Bul CIMM 170*) reports a decreased power consumption per ton of <200-m. produced with low-level operation as well as a substantial increase in capacity; also a decrease in surging, and easier inspection and relining. McClelland (*Bul 342 CIMM 407*) says that in one plant, grinding to 85% <325-m., change to low-discharge operation increased circulating load ratio to 10, decreased overgrinding, increased ball and liner wear slightly, at a new-feed rate of 175+ t.p.d. in a 7×6-ft. (I.D.) ball mill. King and Clemes (*46 IMM 600*) state that moderately low-level discharges are universal on the Rand (except where motors have insufficient capacity) but that at one mill lowering of the discharge lip from 12 in. below the axis to 30 in. resulted in but 6% increase in capacity and an excessive increase in liner wear. Coghill and deVaney (*CEG*) summarize their laboratory indications to the effect that low-level operation with high speeds and high ball loads increases capacity, but that efficiency is better with high discharge and lower

speeds. At EMPIRE STAR (*PC*) the capacities of 7-ft. ×48-in. and 8-ft.×60-in. conical ball mills with reverse-cone grates (Fig. 46) were increased 8 to 10% by raising the discharge height by use of an annular disk fixed in the discharge trunnion. Diameters of discharge opening were thus decreased to 7 and 9 in. respectively. The ball load was also increased proportionately. There was a slight increase in power consumption but a considerable decrease in power per ton ground. At COMBINED METALS REDUCTION Co. (*PC*) similar raises in overflow levels in 8-ft.× 48-in. and in 8-ft.×60-in. conical mills increased capacity 11.5 and 8.5%, respectively; slightly more power and steel were consumed, but power and steel consumption per ton to the same *mog* decreased.

The weight of the evidence would seem to be that low discharge in cylindrical mills increases capacity, by as much as 50% if classifier capacity is adequate; that this increase is probably gained at the expense of a fall in tons per hp-hr. to flotation size or finer and an increase in steel consumption; that it is due in considerable part to the increase in ball or pebble load made possible by grates; and that observation of ball load and pulp density is easier with low-level grates, but that a high-discharge mill is somewhat easier to run.

4. MECHANICAL CONSTRUCTION

Requisites of good construction are (*1*) true alignment of the shell and the supporting elements (trunnion bearings and/or rollers) therefor, (*2*) strength and rigidity sufficient to maintain such alignment with a loaded rotating mill, (*3*) reasonable balance of the rotating assembly exclusive of mobile load, (*4*) a power chain of reasonably high efficiency, (*5*) protection of driving elements and bearings against splash and drip, (*6*) provision for certain introduction of feed, (*7*) protection against wear of barrel by the mobile load, (*8*) means to insure proper action of the mobile load, (*9*) watertightness, (*10*) ease of access for maintenance, (*11*) provision for ready dismantling and reassembly of maintenance parts.

Shell is made of heavy steel plate, usually with welded butt joints. Cast semi-steel shells are also available. Heavy cast flanges for attachment of heads are usually welded to the ends of plate shells, planed with parallel faces which are grooved to receive a corresponding tongue on the head, and drilled by template for bolting to the head. A tight and rigid joint, amply strong against shear, is thus provided. The shell is also drilled by template for liner bolts.

Heads are usually cast semi-steel, ribbed for reinforcement. They may be welded directly to an unflanged shell or machined and drilled to fit shell flanges. TRUNNIONS are usually cast integral with the heads, carefully turned to the mill axis, and highly polished to reduce bearing friction.

Mill barrels are available in which heads, trunnions, trunnion bearings, and shell are made heavy enough to permit extension of length by bolting together two shells.

Bearings. Trunnion bearings are made large to insure low unit pressures. Normally the lower half only is babbitted, the cap being cored out to receive a large body of grease or of waste to absorb liquid lubricant. The lower half is usually of ball-and-socket type for self alignment, but some manu-

c 4 days at 3 in. below centerline and 3 days at 6 in. below centerline. Great difficulty was experienced in retaining balls since the ring grizzly on the discharge had been opened at the end to prevent resistance to the high pulp flow.

facturers recommend rigid bearings. Countershaft bearings are double, ring- or chain-oiling, the two either cast integral with a base plate or machined thereto and provided with set-screw adjustment. The best arrangement from the standpoint of initial and maintained alignment is probably to mount both the drive-end trunnion bearing and the countershaft pinion bearings on one sole plate, the bearing bases being conformed for bolting together across a joint accurately machined for gear-and-pinion alignment.

Gear is bolted to flanges on the shell. On trunnion-type mills it may be attached to either head- or discharge-end flanges, according to convenience of plant layout; with discharge end carried on tire and rollers it is most conveniently placed at the feed end; with four-roller support, it is usually located near the center of the shell. Gears are ordinarily of spur type on small mills and on large pulley-driven mills; they are normally of double-helix Wuest type when the pinion shaft is direct-connected to the motor; either type is used when the pinion shaft is connected to an enclosed reducing gear, which is the preferred modern drive. SPUR GEARS are available in cast iron, machine molded or cut; in cast semi-steel or in cast steel, both cut. They may be cast entire or split. HELICAL GEARS are invariably steel with cut teeth. Flanges of all gears are bored and drilled to template concentrically with the mill axis, and are faced both sides to permit reversal. SPLIT GEARS have the advantage that they permit assembly without dismantling the mill or disturbing the head bolts; their disadvantage, if any, lies in the danger of loosening of the rim bolts, with consequent loss of alignment and probability of breakage.

Spur pinions are invariably steel, usually cast, with cut teeth. HELICAL PINIONS are usually steel forged integral with the pinion shaft and cut.

Drive is various. Old style is by flat belt to a pulley on an extension of the countershaft. Present practice is V-belt drive to a pulley on the countershaft for smaller mills and direct connection to the countershaft through flexible or magnetic couplings for large mills. MOTORS are discussed in Sec. 20, Art. 7.

The CHEAPEST DRIVE, from the standpoint of first cost, is one with a machine-molded cast-iron spur gear on the mill, cast-steel cut pinion, and pulley-driven countershaft. A cast-steel cut gear is mechanically better but more expensive. A long-center horizontal BELT is best from mechanical considerations, but takes up much floor space. With V-BELT drive the motor may be placed in any position with respect to the driven pulley, but on account of splash is best not placed below the mill axis. On account of the heavy starting load, CLUTCHES must be used with belt drives unless the belt and motor are greatly oversize. Any standard friction clutch is satisfactory, but it should be comfortably oversize, (50 to 100%) to withstand excessive starting strains and be well protected against grit. One form has the pulley mounted on a QUILL with a friction clutch. This makes for easier alignment than the ordinary friction-clutch pulley. Rarely a BEVEL GEAR is used in place of a spur gear on the mill but end thrust on the pinion shaft causes difficulty. SILENT-CHAIN DRIVE of the mill countershaft has the same advantage as the short belt and no slip at starting, but is more expensive. No clutch is required for the drive itself, but one must be used in lieu of an oversize motor. GEAR SETS in various combinations are used. The cheapest has the usual spur gear on the mill and a large gear on the mill countershaft, driven, through a flexible coupling, by a pinion on the motor. A more compact but somewhat more expensive arrangement uses a standard gear-speed reducer on the motor, attached through a flexible coupling to the mill countershaft. The gears in the speed reducer are enclosed, run in a bath of oil, and are more efficient and longer-lived than the open gear set first described. Both permit the use of high-speed motors. The most expensive but most efficient drive is a HERRINGBONE GEAR on the mill with a slow-speed motor direct-connected to the pinion shaft through a flexible coupling, ordinarily of the pin-and-bushing type. Speed reduction can be as great as 20 to 1, so that the motor speed required is from 300 to 600 r.p.m., according to the diameter of the mill. This drive showed 10 to 15% saving in power over ordinary belt-driven countershaft and spur gears on conical mills at CALUMET & HECLA (*109 P 759*). Wormser (*114 J 763*) says the opinion is commonly expressed at mills which he has visited that herringbone gears easily make up for the added cost in increased smoothness of operation. Dirt must be carefully excluded. A difficulty with direct connection is the end surge of the mill consequent upon the clearance that must be left between trunnion shoulders and mill bearings to compensate for expansion with temperature rise.

Feeding. The primary function of a feeder is to transport pulp from some receiving point outside the mill into the mill barrel, and to do this smoothly, certainly, and with sufficient driving force to overcome any tendency for the pulp to move in the opposite direction. As secondary functions, the feeder may be required to elevate from receiving to delivery point, to excavate at the receiving point, and to deliver tumbling media as well as ore pulp.

Resistance to introduction of feed is found in the inlet passage, and in a resistance to flow of pulp through the mill that is built up by the discharge arrangements, the tumbling load, and the plastic character of the pulp itself. The greater the sum of these resistances, the more positive the action of the feeder must be. The matter is relatively unimportant with small mill throughputs, but in large mills running with high circulating loads, the feeder is often the bottleneck.

Feeders are almost invariably some form of spiral tube which opens into a hollow cylinder on the axis of the spiral, the cylinder forming an outward extension of the feed trunnion.

Scoop feeder (Fig. 11) is usually built of plate. In the form shown, outside plate *a* forms a one-turn spiral and a little more than one-half of the central cylinder, the remaining shell of which is omitted to permit entry of material from the spiral. Plate *b* and the side plates *c* complete a rectangular spiral tube from inlet *d* to the central tube. This 4-plate assembly is welded together. One end of the central tube is closed by a circular cover plate *f*, bolted to a side plate *c*. A ring *g* is welded to the other side plate and then machined parallel to the plane of the spiral, after which the assembly is drilled to a template and tapped for stud bolting to the smaller end of spool *h*. The assembly comprises the feeder, which is stud-bolted by the other end of spool *h* to the trunnion. Holes *i* are for bolting on a digging and wearing lip.

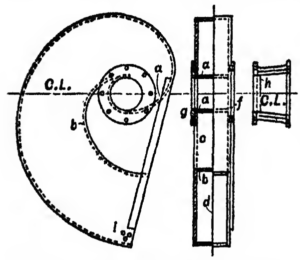

Fig. 11. Steel-plate single-spiral feeder (*after Hardinge Co.*).

The desirable elements in such a design are: generous passages to prevent bridging, at least three times the diameter of the largest feed particle; stiffness, light weight, sufficient turns (at least 1 1/2) to prevent spill-back; sufficient flare of the spiral at the lip to cause some digging, but not enough to cause splash; as great a gradient as possible through the spool and trunnion. The spool and trunnion liners should flare gradually from feeder to mill, if practicable; with a long run here, small diameter, and coarse feed, spiral rifling is necessary, but frequently not sufficient to move large tonnages.

At Asturiana de Minas (*115 J 399*) the capacity of a mill taking 1.5-in. feed was limited by the feeder to 175 tons per 24 hr. The smallest section of the spiral was 5 1/2×6-in. and the opening into the mill trunnion was 7-in. diameter. Capacity was increased to 200 tons by making the thimble between the scoop and the trunnion cylindrical instead of conical and then increasing the diameter of the central discharge opening from the feeder to 9 in. and placing a helix of 10-in. pitch through the feed trunnion. A high-pressure water jet through the spool helps reduce congestion. At Anaconda difficulty in feeding coarse ore was helped by recirculating a part of the mill discharge, which furnished lubrication and suspending power.

Pumping action of a spiral is increased by increase in diameter and number of turns; diameter must be proportioned to mill speed to insure against exceeding critical speeds (see Art. 2 and Sec. 18, Art. 18).

The lack of balance in a single-spiral feeder is undesirable from the standpoint of power draft. For this reason, and in the hope of increasing capacity, double- and triple-scoop feeders have been built. If these scoops are placed in the same plane, the number of turns per spiral must be reduced, with consequent spill-back; if they are placed in different planes, gradient in the spool is decreased, and provision must be made for support of the outer end, or wobble and breakage are certain.

Hines (*59 A 249*) reported a series of tests on scoop feeders from which he concluded: (1) The capacity of a spiral feeder is proportional to the length of the spiral. (2) The capacity of a single-scoop feeder is twice to four times as great as that of a double-scoop, according to the form of the latter. (3) The capacity of a 3-way scoop is about half that of the single scoop. (4) With coarse feeds the capacity of the scoop is limited by the trunnion.

Drum feeder (Fig. 12) is a partial spiral enclosed in a cylindrical or cylindro-conical shell *a*, with opening *b* for receipt of feed and opening *c* for discharge. The space *d* serves to retain feed introduced during the time that the opening of the spiral is above receiving position, thus supplying the necessary storage space to bridge over from the continuous supply to intermittent discharge.

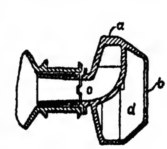

Fig. 12. Drum feeder.

Combination feeder adds a scoop to a drum feeder. The scoop may be mounted on the periphery of the drum or on the spool between the drum and the mill trunnion.

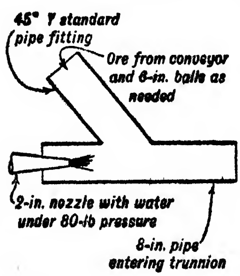

Fig. 13. Sketch of elbow feeder at Hollinger.

Sizes. Scoop feeders are standard in 15, 24, 30, 36, 42, 48, 60, and 72-in. radii and available in any practical radius necessary to elevate sand return from a mechanical classifier. Drum feeders are of relatively small radii, the limiting factor being the provision of sufficient storage in the drum.

Material. Modern practice is to cast the smaller drum and scoop feeders of iron, semi-steel, or steel and to make the larger feeders of both types of steel plate with welded joints, the spool being cast in all cases. Scoop feeders are preferably symmetrical, the spools flanged on both ends, and with a cover plate, thus making them reversible

and consequently adaptable to mill rotation in either direction. Drum and combination feeders are, of necessity, specific to a particular direction of rotation.

Fig. 13 shows a special form of elbow feeder for ball mills. A SCREW FEEDER is sometimes used for soft, dry feed; at the T. P. Kelley & Co. graphite plant (*114 J 325*) scoop feeders failed while this type was successful.

Feed box is required for scoop feeders. It consists of a rectangular box built around the scoop, fitted closely around the spool between the feed trunnion and scoop proper, with clearance all around the scoop circle greater than the largest lump of ore or the largest ball (or pebble) fed. Feed is introduced through suitable openings. If feed is brought into the feed box on the upcoming side in the plane of revolution, the capacity of the feeder is considerably greater than when entry is at right angles to this plane. The top should be protected with a grating.

Choice of feeder. Drum feeders are preferable for coarse dry feeds as they keep large particles out of the feed box and thus avoid digging shocks to both box and feeder. Scoop feeders have the great advantage of serving both as feeders and elevators. The combination feeder has the advantages of both of the others.

5. LINERS

Lining is used on all surfaces with which pulp comes in contact in order to take the wear and thus conserve the strength and tightness of the barrel structure. Shell lining has an important secondary function, *viz.*, to act as the final link in the transmission of energy to the tumbling load. When the load slips, energy input and consequently grinding are decreased. With a smooth liner and hard sand in the mill, slip is slight with a normal load. Gow *et al.* (*112 A 33*) claim that slip is small with smooth liners at 55% of critical, but most operators believe higher speeds than this are necessary with such liners and that rough liners are necessary at this speed. Slip increases with decrease in tumbling load, speed, pulp density, and hardness of ore, and roughness of liner becomes correspondingly more necessary for maximum capacity.

Shell liners usually differ in type according to whether the mill feed is coarse or fine. Such liners for coarse feeds are shown in Fig. 14; those normally used for fine feeds in Fig. 18. It is apparent that liners for coarse feed produce sensible ridges parallel to the mill shell, while those for fine feeds are smooth or uniformly roughened. ROD-MILL LINERS are usually ribbed continuously for the full length of the shell. Ball mills taking coarse feeds are also ribbed, but the ribbing is frequently staggered. Circumferential joints are normally staggered to prevent circumferential grooving. Fine-grinding ball mills are frequently lined with one of the more irregularly roughened liners (Figs. 18 to 21) or with liners that are either smooth or largely smooth but have widely spaced lifters. Pebble-mill liners have the same general surface characteristics as those for fine ball mills.

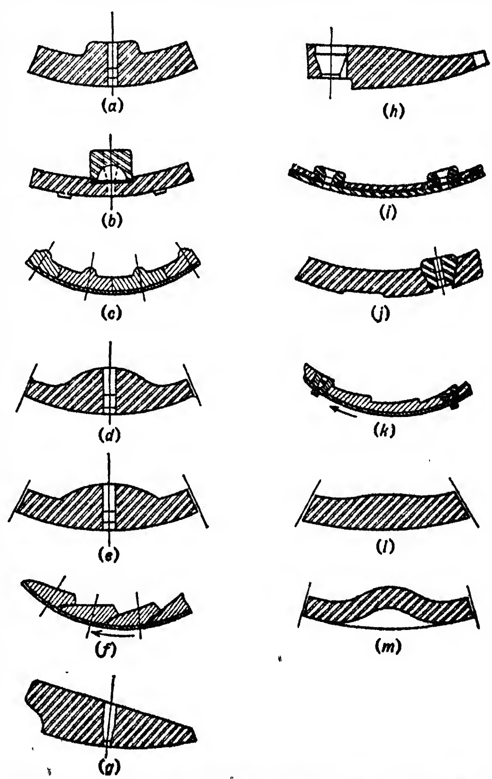

FIG. 14. Liners for coarse feeds (*see also* Figs. 15 and 20).

Size of liners. Shell liners are usually made in blocks or other shapes of such size that they can be introduced into the interior of the mill through a manhole or the discharge-end opening. Maximum weight of individual pieces ranges ordinarily from 120 to 175 lb.; heavier pieces are difficult to handle manually. Ring liners have been used. End liners are sectioned radially or in rings or may be cast in one piece.

Action of ribbed liners. Height, spacing, and conformation of ribs determine the mechanical action of the mill shell on the tumbling charge. The mechanical work of any given part of the liner in a mill properly operated starts as it runs under the toe of the tumbling load. While it is under the load its function is to exert drag on the outer points of the balls of the outer layer so as to cause them to roll on the liner and not to slide. As it emerges from under the load in mills run at cataracting speeds, the liner is expected to throw the media along a trajectory that will end on the toe of the load. The function of ribbing is to aid one or both of these actions of the liner. MAXIMUM LIFT and THROW are attained by lifters of considerable projection and nearly radial sides (Fig. 14, items *a*, *b*), but such lifters substantially immobilize the individuals in the outer layer of media, thus reducing the effective diameter of the mill and, in effect, changing the surface presented to the load to a pebbled or rippled character. Test work at Hollinger (*HS*) indicates that when this is done the grinding is no better than on a smooth liner. High lifters also throw cataracted media in masses, so that they tend to strike the opposite breast, wasting impact and causing an uneven power draft. Maxson (*AIME, Feb. 1941 meeting*) asserted that in a mill grinding 50 t.p.h. change in rib height from 1/2-ball-diameter to 1/3 increased capacity greatly. Hence ribs should be and are kept down, in general, to a projection of less than one-half of renewal-ball diameter, and side slopes are made gradual. Projection is usually less the higher the speed. Some liners are made with ribs having unequal slopes on the two sides; they are designed to permit the steep slope to lead at slow speeds and *vice versa*. At TENNESSEE, using shiplap liners (Fig. 14, items *f*, *g*, *h*), the steep pitch is made to lead in ball mills and follow with rod loads. Projecting wedge bars (Fig. 14, items *i*, *j*) are made reversible to permit longer maintenance of lifting effect.

Wave liners (Fig. 14, items *c*, *d*, *e*) are the type most used in primary mills. They give sufficient lifting effect without immobilizing action on the outer layer of balls. Elevation of the wave crest ranges from very slight (Fig. 14, item *l*) to, perhaps, 2 in. (item *d*).

Shiplap liners are the result of an attempt to reduce the lifting effect of wave liners without, at the same time, encouraging smoothing of the liner by wear. Normal placing of such liners is shown in Fig. 14, item *f*. Much experimentation has been done on these liners to so conform the new inner surface as to prevent high initial wear on the advancing face. The forms shown in items *g* and *h* are those with the best records.

Wedge-bar liners (Fig. 14, items *i* to *m*) are designed essentially to decrease the number of liner bolts per sq. ft. of shell surface. Inner surface at the wedge ranges from smooth in items *l* and *m* to a definite lifter-type in item *i*. The wedge bars are usually made of more resistant metal than the intervening plates.

Wave spacing. When rib projection is less than the radii of the larger media and rib spacing such that the valleys are not over 2 or 3 medium diameters wide, small changes in proportioning make marked differences in medium action and in liner consumption. Howes (*153 A 396*) reports that with the valleys initially equal to three replacement-ball diameters, wear concentrates in the valleys to such an extent that, in one case, while 2 1/4 in. was being worn from the valleys of a block-type liner (Fig. 15, item *a*), the height of the projection was reduced only 1 1/4 in. The projection was at the same time reduced laterally from a plateau to a knife-edge ridge, indicating that the same tendency for wear to concentrate in the valleys persisted as the valleys became wider. On the other hand, Howes reports that with a low-wave liner, the crests of which were originally two replacement-ball diameters apart, wear concentrated on the projections; these wore off with great rapidity, whereupon capacity decreased 15% and the ammeter needle indicated excessive slip. Howes describes also (*U. S. pat. 2 274 331*) a patented liner of his own invention (Fig. 15, item *c*) in which the valleys are about one replacement-ball diameter deep but of such width that only somewhat less than half of a ball volume can seat therein; plateaus are about one ball diameter wide at the top and the distance c–c. of the plateau ridges is slightly more than two ball diameters. The leading wall of the valleys is radial; the trailing wall makes an angle of about 55° therewith. Howes claims both increased capacity and a marked decrease in liner wear (see Table 7) with ball consumption remaining constant.

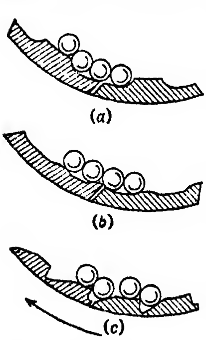

FIG. 15. Howes liners for primary mills.

In 4×10-ft. Marcy rod mills at BERTHA MINERAL CO. (MINE & SMELTER SUPPLY CO., *PC*), doing 2-stage grinding from 1-in. to 48-*mog*, consumptions with different liners were as shown in Table 6. Average life of 10-wave liners was 21 mo.; one 20-wave liner lasted 47 mo.; while the 30-wave liners averaged 44 mo. and one lasted 52 mo. 24 da.

Table 6. Liner wear *vs.* wave spacing

Number of waves	Average wgt. of liners, lb.	Scrap wgt., lb.	% wgt. scrap	Tons crushed	Lb. liners per ton ore	Number of sets tested
10	10,835	3,646	33.6	153,012	0.0708	6
20	11,621	4,360	37.5 *a*	338,328	0.0343	1
30	11,828	3,704	31.3	337,132	0.0351	7

a If scrap weight were the same as 30-wave liner, then scrap loss would be 31.9%. Only one set was tried out.

Spinning impulse of liners. The effect of the slopes of the valley walls on spin of the outer layer of balls may be visualized by step-by-step revolution of a sketch of a ribbed liner around its center of revolution from the position of entry under the toe to the position of departure from the load. It is immediately apparent that the trailing wall of the valley is the effective one. Hence the leading wall should be as steep as possible without forming a sharp corner that will encourage chipping or peening. It next appears that the steeper the trailing wall the more nearly radial its push on ball or rod as it moves under the toe, but the farther above the level of the mill axis it maintains an effective spinning force. The portion of the circumference of a smooth liner over which such a liner can exert effective spinning forces on the balls in contact with it is that subtended by planes through the axis, either side of and below the vertical, which make angles equal to the friction angle with the vertical. Considering steel on steel, the friction angle is about 30°, making about one-sixth of the shell surface at the lower part available to cause spinning of the contacting balls as the mill starts up. Introduction of sand has the effect of decreasing the actual friction angle (or of increasing the apparent angle), and thus increasing the effective fraction of the circumference. But in an operating mill with a smooth liner the load, of course, shifts toward the rising side until a considerable part of the raised portion is above the level where any effective spinning work is done on it by the shell. However, by inclining the trailing edge of the liner valley to an extent roughly equivalent to the angular shift of the surface of the load, the slopes of these trailing walls on the rising side relative to the horizontal are decreased and effective slopes therefore persist for all or a considerable portion of an angular distance equal to the slope given them. The Howes liner when new, with two slopes on the trailing wall of the valleys and the tops of the plateaus tangent, insures that at least one ball out of each group of three adjacent to the shell will be receiving a spinning impulse over an arc of about 90°. Spin from the shell is relatively unimportant under the toe, since this part of the load is already active by avalanche action. Hence the steep slope of the trailing wall relative to the horizontal results in no serious loss of effective activity at this point, and is advantageous in catching balls at the outer end of the toe and pushing them back into action.

The shiplap liner and the modifications thereof patented by Howes (Fig. 15, item *c*) embody these principles of valley slopes. Howes decreases valley wear by narrowing the valleys, while at the same time supplying a broad enough peak to prevent formation of a residual knife-edge. As a result wear is said to produce finally a short-wave or undulating liner with the final ridges underlying the troughs of the original valleys.

Straub liner has spiral ribs on the shell, so placed as to throw material, both balls and pulp, away from the grate back toward the feed end. The purpose is to keep large balls away from the grate, both decreasing hammer thereon and putting the larger balls where they can do more good.

Effect of liner on character of product. At CONSOLIDATED MINING & SMELTING CO. (*33 CEMR 139*) it was found that with new ribbed liners the mill discharge was definitely granular; as the ribs wore down there was more sliming and increase in the percentage of coarsest sizes in the product

Material for ribbed liners is almost invariably manganese steel in rod mills and in mills fed with balls larger than 2-in.; with smaller balls chilled cast-iron liners, which are much cheaper in first cost and which normally, also, are cheaper per ton of ore ground, are often used, but if maximum unit capacity is sought, manganese steel predominates in this service also on account of its longer life and the consequent reduction in lost time for relining. SUPER-MOLYCHROME liners made of an electric-furnace alloy steel with Mn, Cr, and Mo the added metals, heat-treated to 450 Brinell, have been used in a number of mills; a small amount of comparative data are given under "Wear," p. 21.

Composition of manganese liners and their heat treatment are both of major importance in obtaining long life; of the two the heat treatment is the more critical, since a liner of suitable composition can be ruined by improper heat treatment. Thus, although properly treated manganese-steel liners will invariably outwear hard white iron, at TONOPAH BELMONT (*52 A 95*) manganese liners in tube mills lasted 16 1/3 mo. and cost 6.4¢ per ton

ground, while hard white iron lasted 2 yr. and cost 1.7¢. The liner should be tough and as hard as it can be made without substantial sacrifice of toughness. These properties are imparted principally by the heat treatment.

End liners are used solely for protective purposes and are, therefore, usually smooth. Their FORM is based on consideration of ease in handling; their THICKNESS on an attempt to balance against shell wear in order to make replacement times correspond. Wear is much less than that of shell liners, hence at some mills end liners are made of chilled cast iron when shell liners are manganese steel. At HOLLINGER (*HS*) head-end liners usually wore more rapidly than discharge-end in ball mills but not in rod mills. Wear is normally greater at the center than at the periphery. For overflow mills which are lined without removal of the ends, the end liners are made keystone-shaped; if an end is open at relining time, one-piece liners or, as at HOLLINGER, ring liners are used. End liners are sometimes ribbed radially.

Thickness of liners of the type shown in Fig. 14 determines the interval between replacements and, in the case of the shell liners, the extent of variation in critical speed, weight of tumbling charge, charge action as determined by liner-surface conformation, capacity, and power consumption during this interval. These factors are of great importance. Thus in a 6-ft. mill a 3-in. wear of liner will mean an increase of more than 3% in the percentage of critical speed for a mill operating at 24 r.p.m.; the tumbling charge will need to be increased up to 15% of the original charge over the period in order to maintain 45% of mill volume; and capacity and power consumption should increase about 23% as compared with the new-liner figures, if charge volume is maintained. New thickness normally ranges from 2 to 4 in. in the valleys, being greater the less the rib projection.

Effect of wear on operation. Liner wear has, as above noted, a material effect on power consumption and capacity through its effect on internal diameter of shell. The magnitude of the effect for any given mill may be estimated, neglecting simultaneous changes in slip due to changes in liner surface and peripheral speeds, by applying the equation

$$C \propto P \propto D^{2.6}$$

where C = t.p.h. to a given product size (Art. 14), P = net power consumption, and D = internal diameter of mill.

At LAKE SHORE (*LSS*) power and capacity of a 5×16-ft. mill increased gradually up to 135% of the values with a 3 1/2-in. new liner during wear to 1/2-in. thickness; for a 6×16-ft. mill the increase was 28% for the same wear, and for a 7×6-ft. mill there was an increase of 20% during a wear from 3 1/2-in. to 3/4-in. thickness. The LAKE SHORE tests further show that liner wear itself increases as an exponential of the diameter, probably near $D^{2.6}$.

Liner wear must also be taken into account in setting up power-draft controls for feed rates (Art. 18) and in making schedule for renewal of grinding media (Art. 6). In view of these variations, usual practice is to limit wear to about 1 1/2 to 2 1/2 in., which entails a scrap loss of 35 to 50%, according to mill diameter. New liners 3 to 4 in. thick are required to give these wears and at the same time insure against break-through to the shell at bad spots. Smooth liners are sometimes made as thin as 2 in., and occasionally liners are cast as thick as 6 in. at the ribs. Some mills make periodic inspections of liners, *e.g.*, at 2-week intervals (*IC 6757*), in order to permit greater wear, but the danger of breakage of thin plates is so great, so difficult to discover in some cases, and shell wear and weakening so rapid under a broken plate that most operators will not take the risks.

Trunnion liners have a smooth inner surface, or are provided with helical ribs arranged to accelerate entry at the feed end and to hinder discharge (and aid ball entry) at the discharge end. They are invariably of slip-in ring construction, held by bolting or cementing (see discharge- and feed-end liners respectively in Fig. 25) or by abutting against adjacent liners. They may be cylindrical or flared on the inner surfaces. Since they can usually be replaced from the outside, and consumption is small, their design is important primarily from their effect on flow and ease of installation.

Liner bolts. Liner plates are ordinarily bolted in, although keyed-in shell liners have been described (*134 J 25*), and many mills are lined with plates held in by bolted wedge bars (Figs. 14 and 18). Bolts are of steel of high tensile strength, forged to a tapered head of square, rectangular, or oval section to draw down into a correspondingly cast seat in the liner plate. Threads should be heavy and of low pitch. Bolt diameter should be ample to withstand tightening with the heaviest two-man wrenches. Fiber or metal packing is used under the nuts. Bolt holes should be drilled to a snug fit. New liners should be run dry with a light load for several hours, then with water as an indicator, and the bolts re-tightened as necessary before feed is turned in.

Backing is frequently used behind shell liners to prevent breakage with severe impact conditions or when cast-iron or thin alloy liners are used; it also protects bolts and shell from wear by sand which penetrates between liner blocks. One-inch plank is the usual backing material; zinc has been used in the FLAT RIVER mills and at BALMAT. Rubber in sheets 4×12-ft.×1/4-in. was used for the high-speed rod mills at TENNESSEE (*153 A 345*) because it gave a larger working diameter and correspondingly greater capacity.

Blocking is often employed behind the liners to reduce interior diameter. The usual procedure is shown in Fig. 16. The practice is more economical than simple removal of tumbling media when reduction in capacity over a considerable period is desired. It has also been followed in many cases when changing from pebble to ball loads, especially when fears were entertained as to the ability of the shell to carry full ball loads, or when insufficient motor capacity for the larger loads was available.

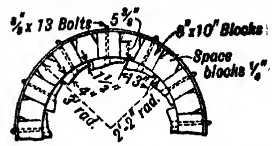

FIG. 16. Method of reducing diameter of a cylinder mill (*after Daman*).

Wear of ribbed liners, as reported for several hundred rod and ball mills, is highly variable, ranging from 0.003 to about 1.0 lb. per ton of new feed ground. When exceptionally high and low figures are discarded, the mean and average figures fall at about 0.25 lb. per ton for shell and end liners combined, scrap loss included. There is no difference between the wear figures for white-iron and alloy steels when these are taken for the plants as a group, probably because cast iron is used for the easy duties. Comparative wears and costs at particular mills are given in Tables 7, 8, and 9.

Table 7. Wear of shell liners at Mammoth (*After Howes*)

Mill	Type of liner *a*	No. of sets	New weight, lb., aver.	Life, days, aver.	Consumption, lb. per ton *l*	Relative consumption per ton
5×10-ft. open-end primary mill *m*	Block, solid *d*	1	20,331	92 *c*	0.394	100
	Block, slotted *b, d*	1	18,510	104 *c*	0.318	81
	Undulating, slotted *e*	1	20,908	63 *f*	0.593	150
	Special *g*	1	26,000 *h*	115	0.403	102
	Howes, slotted, gusseted *i*	1	18,606	120 *j*	0.277	70
	Howes, slotted *t*	5	17,950	128	0.250	63
	Howes, solid *t*	1	19,119	210 *k*	0.162	41
64 1/2 Marcy secondary mills *p*	Block, solid *g, q*	2	10,198	272	....	100
	Shiplap, solid *r*	1	8,694	232	....	100
	Shiplap, slotted *r*	3	8,366	241	....	93
	Shiplap, spiral, solid *r*	1	8,700 *n*	252	....	92
	Howes, slotted, narrow ridge *s*	1	7,515	221	....	91
	Howes, slotted *t*	1	9,632	363	....	71
	Howes, slotted *t*	1	9,632	383 *o*	....	67

a All liners of manganese steel.
b To improve heat treatment, 1 1/4×12-in. slots were cast extending from the face to within 1 1/4 in. of the back of the liner; arranged longitudinally in three parallel rows, one at the center each of the plateau and the two valleys; 2-in. webs between the ends of slots; weight reduction, @ 9%.
c Thickness at discard: Ridge, 3-in. knife edge; valley, worn through.
d See Fig. 14, item *a*. Ridge, 4 1/4 in. thick, valley 2 1/4 in., new. Capacity abnormally low during first 3 weeks of life; appreciable improvement after leading edge of ridge had worn off.
e See Fig. 15, item *c*. Five rows of slots. Ridges 4 1/4 in. thick, valleys 3 3/4 in., new. (See note *b*.)
f Life of ribs, 4 weeks, during which time capacity was normal. Thereafter slip was excessive, capacity dropped 15%, the liners grooved circumferentially, and wear increased tremendously (3 1/4 in. wear in 5 weeks).
g Originally undulating, slotted. See note *e*. After 33 days' wear, manganese-steel lifters were plug-welded on, making essentially a block liner. *h* Estimated; see note *g*.
i See Fig. 15, item *c*. Gussets 5 1/2 in. wide and flush with the ridges at the top were cast across the valley at the third points. Two rows of slots, one down the center of each ridge.
j Wear over the gussets was 3/8 in. deeper than elsewhere, amounting to about 10% increase. The webs between the slots stood up above the remainder of the worn ridge.
k Increased wear due to elimination of spalling and peening at the edges of the slots. Consumption per ton of feed 59% less than with solid block liners.
l Including scrap loss.
m 560 tons per 24 hr.; rhyolite, andesite, and granite gangue, highly abrasive; feed, <1/2- or 5/8-in.; product, <8-m. Renewal balls, 4-in. forged steel. Speed, 80% of critical. Operation, closed-circuit with 8-m. screen. *n* Estimated. *o* Estimated after 293 days.
p Two mills in parallel closed circuits taking <8-m. Dorr classifier sands and grinding to 90% <65-m. Renewal balls 2 1/2-in. forged steel or 2/3 @ 2 1/2-in. and 1/3 @ 2-in. cast-iron. 80% of critical speed.
q Wear concentrated at joints and in valleys. Scrap loss high. Capacity low when new.
r Variation in capacity during life less than with block liners.
s Ridges too narrow (1 1/4 in. wide at top); they wore to a knife edge and peened over rapidly.
t Variation in grinding capacity during life slight. Ball consumption constant throughout tests in primary mill; 6% reduction in secondaries.

At the PRESIDIO mine (*W. E. Moore, PC*) Hardinge mills in primary service with 3 1/2-in. cast-iron ball renewals and Super-molychrome liners averaged 0.154 lb. total liner per ton in 1940 at a cost of 2.1¢ per ton. Average cost for the 5 years 1936 to 1940 was 2.2¢ per ton. Life was about 80,000 tons of new feed per set. Ball consumption was 2.04 lb.; cost 4.6¢ per ton. Consumption of white cast-iron liners in secondary tube mills was 0.40 lb. per ton at a cost of 1.8¢ per ton; 2 1/4-in. cast-iron renewal balls wore at the rate of 1.7 lb. per ton and cost 3.8¢ per ton. At a mill grinding moderately hard lead-zinc-pyrite ore, manganese-steel liners averaged 103,837 tons per set as against 113,476 tons for Super-molychrome (*PC*). C. F. Thompson (*PC*) states that in a 6×6-ft. Marcy mill on one ore, a set of manganese-steel step liners weighing 13,000 lb. treated 67,000 tons, or 0.19 lb. per ton; a set of block liners weighing 15,365 lb. ground 84,000 tons, or 0.18 lb. per ton; and a set of the same liners cast with pockets weighed 13,896 lb. and treated 98,000 tons, or 0.14 lb. per ton.

Table 8. Wear of manganese-steel end liners in 5×10-ft. open-end primary ball mill at Mammoth (*After Howes*)

Type of liner	Consumption, lb. per ton of new feed	No. of sets	Weight, new, lb. *f*	Life, days	Relative consumption per ton of new feed
Smooth *a*	0.040	3	1,800 *e*	80	100
Ribbed *b*	0.024	2	1,980	146	60
Multiridged *c*	0.022	1	1,730	142	54
Howes, slotted *d*	0.017	1	1,955	209	42

a Somewhat thicker at center when new.
b 12 radial ribs, 2 1/2 in. wide, 1 1/2 in. high.
c Light ribs radiating to the ridges of the Howes shell liners.
d Ribs of width equal to those of Howes shell liners (@ 4 in.) with V-section valleys, radiating to ridges of Howes shell liners.
e Estimated.
f One end only.

Wear increases more rapidly, in general, with increase in speed and mill diameter than capacity does. It increases, normally, with decrease in pulp density, with increase in size of feed, with decrease in height of discharge, with increase in diameter and in hardness of tumbling media, and, of course, with increase in hardness of ore. Variation with design of liner has been described (see also Tables 7 to 9).

Table 9. Ball-mill liner wear at one plant *a* (*PC*)

Material	Total weight	Total cost	Cost per lb.	Days run	Tons ground, total new feed	Cost per ton ground	Lb. per ton ground	Scrap loss, %	R.p.m.
White iron	17,500	1,050.00	0.060	137	22,583	0.0465	0.775	50	26
White iron	17,500	1,050.00	0.060	99	34,000	0.0309	0.515	50	26
Super-molychrome	18,480	1,755.60	0.095	122	38,300	0.0458	0.482	42	26
Alloy 18	20,024	2,070.44	0.105	152	51,030	0.0405	0.392	36	24 1/2

Ni-hard	19,958	1,995.80	0.100	153	47,270	0.0422	0.422	40	24 1/2
White iron	17,500	1,050.00	0.060	123	23,438	0.0449	0.746	50	26
Manganese steel	21,910	2,331.23	0.106	202	66,836	0.0349	0.329	36	24 1/2

a Mills, 7-ft. × 48-in. Hardinge; 28,000-lb. ball load; replacement by addition of 4-in. forged-steel balls; grinding from <1-in. to 28 *mog;* ore, soft relatively.

Comparative wear of liners. Shell-liner wear is greater near the head end of the longer primary mills, wear of feed-end liners is generally greater than that of discharge-end, and wear near the center of the feed-end liners greater than that near the periphery. Thicknesses should be adjusted accordingly.

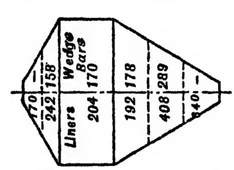

FIG. 17. Comparative life (days) of cast-steel liners and wedge bars in different parts of a conical ball mill.

At HOLLINGER (*HS*) the life of the 3 1/2-in. outer head-end ring was 250 days; inner, 125 days; discharge-end annular lip, 750 days. At WALKER MINE (*IC 6555*) consumption of manganese-steel shell liner was 0.27 lb. per ton as against 0.18 for feed-end liner. At MAGMA (*IC 6319*) manganese shell-liner wear in primary service was 0.15 lb. per ton and head-end wear 0.05 lb.; in secondary mills the corresponding figures were 0.06 and 0.03 lb. and 0.04 lb. at the discharge end. MIDVALE (*IC 6492*) reported 0.19 lb. for manganese shell liners and 0.02 lb. for manganese or chrome ends.

Comparative wear in different parts of a conical mill is shown in Fig. 17 (ENGELS *IC 6550*). At MT. ISA (*IC 7073*), comparative lives were as follows: Primary mills: feed cone, 1.0; cylinder, 1.07; discharge cone, 1.28. Secondary mills: feed cone, 1.0; cylinder, 1.14; discharge cone, 1.28. Secondary: primary = 1.28 : 1. At TYBO (*IC 6430*) the consumption in the feed cone was more than twice that in the cylinder.

Liners for fine grinding are shown in Fig. 18. SMOOTH-PLATE LININGS are usually from 1 to 2 in. thick. They may be drilled for bolting directly to the shell or be of wedge-bar type as item *a*. Plates give the largest possible internal diameter in the mill. They tend to wear into circumferential grooves, after which grinding normally improves.

Smooth white-iron plates, 1 1/4 in. thick, 8 in. wide, and 48 in. long in a 5×22-ft. mill taking 2 1/2-m. feed at the BUTTERS VIRGINIA CITY mill lasted 9 mo., which was as good as the El Oro would do, and the plate lining was the cheaper (*89 J 905*). At RAINBOW mill (*99 J 1104*) the 1 1/2-in. cast-iron feed-end liner lasted 6 mo. The discharge-end liner lasted longer; 1 1/2-in. shell liners lasted 13 mo. Relining required 14 hr.

Cost of smooth liners and other wearing steel in HOLLINGER ball mills (*HS*) was as follows: Shell liner, Mn steel, life 297 da., $15.54 per day; head-end liner, Mn steel, $2.00; discharge end, Mn steel, $0.34; grates, cast iron, first cost, $0.17; grates, resurfacing with hard alloy, $0.90; scoops, lips, $0.22; scoops, lining, $0.29; total $19.46 per day or 1.36¢ per ton.

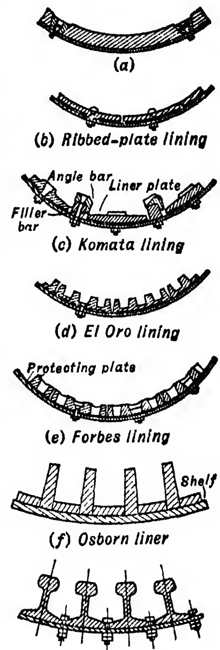

FIG. 18. Liners for fine grinding.

Circumferential grooving indicates frictional drag at the outer surface of the outer layer of balls, and is definite proof of sensible slip, with consequent decrease of energy input to the load. The fact that the rate of wear decreases and grinding capacity rises after the grooves have worked into an originally smooth liner is due to increase in effective spin-producing contact of the ball races in the liner with the outer balls. Circumferential grooving does not occur with flint pebbles and metal liners.

Black liner is a plate liner cast with circumferential grooves spaced to accommodate the largest renewal balls. Tests at WRIGHT-HARGREAVES, which led to its adoption there, indicated an advantage in capacity upon the installation of new liners as compared with new smooth liners (before grooving had occurred by natural wear). The same advantage was reported from LAKE SHORE (*LSS*). At CHINO they were tried on <1/2-in. feed when grinding to 65 *mog* with 3-in. balls and were found to be not so satisfactory as wave liners.

Ribbed-plate liner (Fig. 18, item *b*) or a wedge-bar plate liner with only a slight projection of the wedge bar is used when it is desired to increase lift or decrease onset of circumferential grooving.

Komata lining is substantially a ribbed-plate lining with replaceable ribs. See Fig. 18, item *c*. It was first introduced in New Zealand and used almost exclusively there both for pebble charges and for ball charges up to 3-in. size, both wet and dry grinding (*24 CMI 192*). It is made up of plate liners alternating with rib liners about 18 to 20 in. apart. The rib bars are made up of two parts, a cast-iron base and a special steel wearing top that is reversible and readily replaceable. In one type (wedge-bar) the rib bars are wedge-shaped and hold in the plates so that the number of bolts is reduced. Plates are 3/8 in. thick at the edges and 1 in. at the center. Maximum wear comes on the angle bars and the use of separate wearing parts effects a considerable economy in the amount of metal that must be discarded. Raised bosses are provided around the bolt holes to prevent cupping, and joints in the bars are staggered to prevent circumferential grooving. With cast-iron plates a low boss is put on the back to protect the plate against breakage when the bolts are tightened. Brown, the inventor, recommends (*104 P 206*) lower speed and lower pebble load than with smooth liners of the El Oro type on account of the greater lifting effect of the ribs. At TONOPAH BELMONT (*52 A 112*) Komata manganese-steel lining cost (1913) $1,785 installed, including $145 for labor. After 16 1/3 mo. new ribs were put in at a cost of $273 and lasted 10 mo., when the whole lining was removed. Cost per ton ground for this lining was $0.0457. A locally cast hard white-iron ribbed liner costing $712 in place lasted about 2 yr. and cost $0.0173 per ton. Silex (4×4×8-in. blocks) cost $396 in place and lasted 8 mo., making the cost $0.0583 per ton ground.

Silex lining is a smooth lining composed of blocks or bricks of hard flint, normally 6 to 9 in. long, 4 or 5 in. wide, and from 2 to 4 in. thick. It is used only with pebbles. Uniformity in thickness is the important requirement, but considerable variation in length and width is allowable. The blocks are cemented into place with Portland cement. Joints are staggered to prevent circumferential grooving.

A 5 1/2×22-ft. mill on the RAND has been relined in 18 hr., but the usual time is 24 hr. from stopping to re-starting, including 4 hr. steaming (*RMP*). The cost of installing silex lining (4×4×8-in. blocks) in a 5×18-ft. mill at TONOPAH BELMONT in 1913 (*52 A 112*) was: Silex, 12,300 lb., $258; cement, 33 sacks, $36; labor, $102; total, $396. Silex lining can be worn down to 1 1/2 or 2 in. before it is necessary to replace it. Average life on the Rand was from 60 to 150 days, depending on the thickness and the conditions of operation. At the TREASURY mine (*So. Af. Ass'n Eng'r's, Apr., 1905*) silex lining lasted 2 1/2 times as long as smooth cast-iron and cost half as much. With thick blocks, which have the longer life, the diameter of the mill is materially decreased when the blocks are new as compared with the

diameter when the blocks are old and there is consequently a marked change in peripheral speed of the mill during the life of the liner. With a new liner, horsepower, pebble capacity, grinding capacity, and grinding efficiency are less than with a worn or thinner liner. It is necessary, therefore, to balance the cost of more frequent renewals attendant upon the use of thinner blocks against the decreased efficiency in the early part of the life of thick blocks. To compensate for greater wear at the feed end one plant (*7 JCM 368*) lined the first 7 ft. with 8-in. block, then 7 1/2-in. for 1 ft., 7-in. for 1 ft., and 6-in. for the balance of the length. Ironite is similar to silex, except that the material used consists of blocks of hard trap rock. In some localities where hard, close-grained rocks are obtainable locally, these are used in place of silex. Silex was more generally used than plate liners. The principal disadvantages of the stone-block type of liner are the great reduction in mill volume and the variation in volume, power consumption, capacity, and efficiency between new and old liners. These are sufficient to bar such liners in most modern ore-treatment plants, but their use is commonplace in grinding nonmetallics when contamination with iron would be undesirable.

Barry lining consists of silex blocks cemented into a sectional iron honeycomb.

Plymouth lining (*101 J 263*) is made of pieces of semi-steel battery liner, roughly 4 in. wide and 12 to 36 in. long, and pebbles, cemented in.

A special lining for a 4×10-ft. ball-tube mill at Liberty Bell was made by cementing in alternate courses of 1 3/4×2×5×48-in. hard-chilled cast-iron bars and 4 1/2×5×8 1/2-in. quartzite blocks, set with the 4 1/2-in. dimension radial; no bolts were used. For one lining, 200 quartzite blocks, 42 ribs, 9 sacks of cement, and 9 sacks of sand were required. Consumption was 0.65 lb. quartzite and 1.25 lb. iron per ton of new feed.

El Oro, Forbes, Osborn, and Komata liners have been widely used in American mills. El Oro liner (Fig. 18, item *d*) consists of grooved plates bolted to the shell of the mill, the width of the grooves being about the medium dimension of the larger pebbles used. In operation these larger pebbles wedge into the grooves and the liner surface soon becomes an irregular one of pebbles that protect the metal ribs from wear. As pebbles wear down and are broken they fall out and are replaced by other pebbles. El Oro liner plates are made of cast iron, cast steel, or special steels.

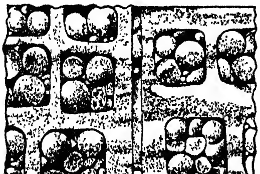
Osborn liner (Fig. 18, item *f*) is a modification of the El Oro in which hard-steel ribs are wedged into place by mild-steel wedges, both being set in cement mortar. There are no bolts. Pebbles fill the spaces between the ribs and take most of the wear. This liner was much used in South Africa. At Simmer and Jack (*RMP*) a mill with Osborn liner had a duty of 139.5 tons containing 57.2% <90-m. while an adjoining silex-lined mill ground 133.5 t.p.d. to 54.6% <90-m. Ribs wear most rapidly at the fed end and after initial wear at this end are reversed. Sectional bars (three lengths to a course) permit more economical replacement for head-end wear. Life is about 300 days. One man can reline in 12 hr. (*97 J 465*).

Forbes lining (Fig. 18, item *e*) is the same in principle and similar in appearance to the El Oro lining. It differs from the El Oro in that the plates are cast in the form of a curved grid and are bolted against a back plate that protects the shell at the bottom of the openings in the grid. Life at Nevada Packard in a 6×10-ft. mill making 75% <200-m. was 345 days as compared with 220 days for a step liner of approximately the same weight.

Globe lining (*98 J 393*) is of the general El Oro type but with circumferential grooves tapering toward the base and also tapering longitudinally in a direction opposite to the direction of rotation. The original pebble load should be a good mixture of all sizes in order to insure quick filling of the liner grooves. Life at Hollinger was reported as 3 mo. greater than that of El Oro lining. Weight of metal for a 5×20-ft. mill is 15,500 lb. Relining requires 6 men 12 hr.

At Hollinger (*HS*) side-by-side tests were made on different liners with 6×16-ft. pebble mills. Once optimum speed was established, no difference in capacity was observed with Globe, El Oro, Cobalt pocket, or smooth liners.

Fig. 18, item *g* (*122 P 465, 112 J 778*) shows a lining made of steel rail, designed to pick up a ball layer in the same way that the El Oro lining picks up pebbles. Lining for a 6×5-ft. grate mill using 4-in. balls and crushing <1-in. material is composed of 50-lb. re-laying rails with 7/8-in. bolts. A complete liner cost about $250 (1921), which was one-tenth the cost of a manganese-steel liner. It lasted 5 mo. on open-circuit work grinding to <1/8-in. The cost of balls lodged in the liner must also be charged. A similar lining in a 5×6-ft. center-discharge regrinding mill (<1/8-in. to 95% <100-m.) lasts about 15 mo. using 2-in. balls. A white-iron plate lining in the same mill lasts about 5 mo. and costs twice as much.



(*a*) *Cobalt*

(*b*) *Clover-leaf*

Fig. 19. Pocket liners.

Pocket liners are castings with steep-walled pockets in which the grinding media wedge. The Cobalt liner has square pockets (3 to 4-in.) distributed as shown in Fig 19, item *a;* the clover-leaf liner has smaller pockets shaped and arranged as in item *b*. It is reported

from LAKE SHORE (*LSS*) that at proper speeds grinding capacity with pocket liners in a given mill is not different from that with smooth liners. Step or shiplap liners with longitudinal slots in the heel tend to pick up balls and maintain a roughened surface along the line of the step.

Britannia lining (Fig. 20) consists of 3 to 4-in. pieces of old railroad rails set on end in cement.

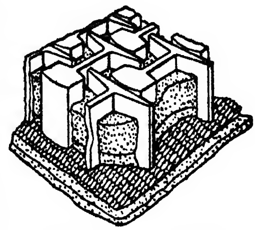


FIG. 20. Britannia liner.

Line the mill in sections as follows (*99 J 239*): First spread a layer 1 in. thick of cement mortar (1 cement to 2 of sharp, clean sand), press down sections (not to exceed 1 × 2 ft.) of 4- to 8-m. wire screen, then a second 1-in. layer of mortar into which the rail ends are forced as far as possible, then more mortar to within 1 in. of the top of the rails. Allow to set, then turn the mill to line another section. When starting up, run for a few hours with lump ore but no balls or pebbles to allow crevices to fill. Cement wears sufficiently more rapidly than steel so that the ends of the rails project and make the lining surface irregular. In later practice with larger mills at BRITANNIA (*IC 6619*) the rail was hot sawed in 7-in. sections and hardened by quenching. It was removed at 2 to 3-in. thickness after 2-yr. life.

Rail-cement lining used for 6 or 10-m. and finer feeds at UTAH, RAY, and CHINO comprises the same arrangement of 6 or 7-in. @ 90-lb. rail sections for the shell as is shown in Fig. 20 except that the wire reinforcing is omitted and the cement is filled in flush initially.

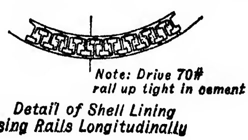

FIG. 22.

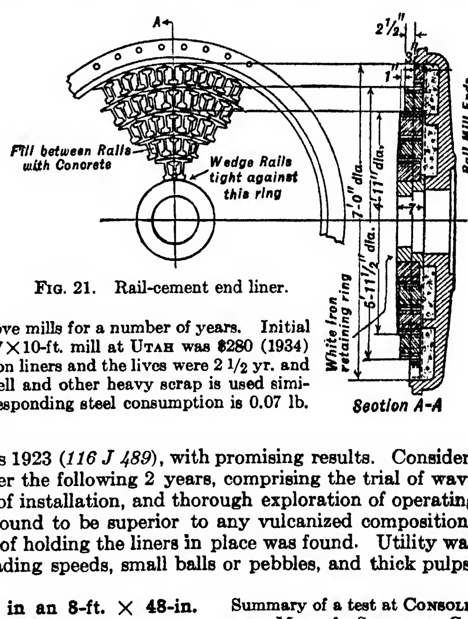

FIG. 21. Rail-cement end liner.

Fig. 21 shows the same lining applied to the head, graded radially for severity of wear. Fig. 22 shows a modification of the shell lining for longitudinal setting of the rails.

These linings have been used at the above mills for a number of years. Initial cost of the rail liner (Figs. 20, 21) for a 7×10-ft. mill at UTAH was $280 (1934) as against $1,100 for a set of white cast-iron liners and the lives were 2 1/2 yr. and 1 yr. respectively. At RAY scrap roll-shell and other heavy scrap is used similarly and a life of 2 yr. is reported; corresponding steel consumption is 0.07 lb. per ton.

Rubber liners were tried as early as 1923 (*116 J 489*), with promising results. Considerable experimental work was done over the following 2 years, comprising the trial of wave and smooth forms, various methods of installation, and thorough exploration of operating conditions. Pure gum rubber was found to be superior to any vulcanized compositions tried. No fully satisfactory method of holding the liners in place was found. Utility was definitely limited to fine feeds, cascading speeds, small balls or pebbles, and thick pulps.

Table 10. Rubber *vs.* steel liners in an 8-ft. × 48-in. conical mill at Consolidated Mining & Smelting Co.

	Steel liner	Rubber liner	
Speed, r.p.m.	18.1	18.1	20.4
Tons new feed per hr.	98.2	96.0	99.4
Horsepower consumed	123.2	98.7	117.3
Per cent. solids	76.1	77.8	76.8
Per cent. <200-m. in feed	36.8	36.8	35.2
Tons <200-m. produced per hr.	7.0	6.1	6.5
Tons <200-m. produced per hp-hr.	0.058	0.062	0.065

Summary of a test at CONSOLIDATED MIN. & SMELTING CO. (HARDINGE CO., *PC; 33 CEMR 139*) is given in Table 10. The power consumption indicates greater slip with the rubber liners; the drop in production of <200-m. with the rubber liners is roughly proportional to the fall in power draft, although a slightly higher efficiency is indicated for the rubber. No properly comparative data on wear are available, but the indications are that the life of the rubber, even assuming non-collapse of the lining, is not sufficiently greater than that of steel to compensate for the great difference in price. The complete lack of adoption over a period of 20 years is convincing evidence of the present superiority of the metal liners.

Choice of liner is based on the kind of tumbling medium, the charge action desired, the sizes of feed and product, the hardness and toughness of the ore, the relative importance of capacity and grinding efficiency, availability of materials, and cost. Any one factor may predominate in a given case. In general, ribbed liners are used for coarse feeds, non-ribbed for fine products, and smooth for ultra-fine products. Alloy steels are used when impact loading is heavy, cast iron or the self-renewing (El Oro) types for light loading, *i.e.*, small or light media and/or noncataracting speeds. High freight rates combined with local availability of metal scrap encourages the use of cast-iron or cemented-scrap linings. When high capacity is important, alloy linings are usually used on account of their capacity to withstand severe operating conditions, and the longer intervals between relining. Per-ton cost of liner is relatively small in any case, and is determining only when the operation is large and has settled down to the point where fractions of a cent per ton ground are important.

6. TUMBLING MEDIA

The tumbling load is the working part of the mill. It draws substantially the same amount of power whether it does any useful work or not. The amount of useful work that it does differs with the shape of the tumbling bodies, their size relative to the grains being ground, their quantity, and the kind of material they are made of. Loss by wear is one of the principal items of grinding expense. Hence all of these items are of vital importance to efficient operation.

Shape. Cylindrical rods, spherical balls, and, to a lesser extent, rounded pebbles are the media used in substantially all mills today. Practically all conceivable shapes have been suggested and many of them tried over the past 20 years: present-day practice represents survival of the most effective and at the same time the cheapest to provide.

Shape determines interstitial volume of the load and thereby affects both medium weight and ore weight per unit of struck volume of load. Rods occupy the greatest percentage of struck volume, spherical balls the least. Hence rods exert greater pressures at a given depth of loading than balls. They also give a shorter in-mill time per pass for a given throughput, all other things being constant.

Cascading individual rods strike heavier blows than balls because of their greater mass. On the other hand, when the avalanche effect in a cascading load is considered, it is not improbable that greater concentration of load occurs with balls. The same is not improbably true in the rubbing zone. The added mechanical advantage of free-fall hammering is not availed of with rods on account of the tendency for the load to tangle at cataracting speeds. Rods should be given more end clearance with coarse than with fine feeds to overcome an increased tendency to tangle.

Experience indicates that rods are superior to balls for feeds in the range from $^1/_2$-in. to 1-in. maximum when the mill is not called upon to finish at sizes finer than 14-m. Balls are superior at coarser feed sizes or for finishing 1-in. feeds to 28 *mog* or finer, because the mill can be run cataracting and the large lumps broken by hammering.

Surface is the characteristic of the medium that predominates in fine grinding. Balls have, of course, greater surface per unit of weight than rods and excel them for fine finishing. Cubes (*Norges Tekniske Hoiskole (1935) 581*), tetrahedra, and irregular worn balls (*CEG*), cones and disks (*124 J 695*), all of which have greater surface per unit of individual weight and of charge weight than balls, have, however, proved less efficient in fine grinding. The reason lies, probably, in the decreased rubbing activity in the load. The irregular shapes draw more power for a given speed. Coghill and deVaney found that worn and irregular balls from an old load were about 6% less effective in surface production than new small balls. Rose (*123 J 49*) tested hexagonal rods. He found some evidence of a more granular product when the rods were new but found that they soon wore to perfect cylinders.

Size of media most suitable for a given tumbling mill in a given service has provoked more discussion than any other characteristic of the tumbling charge, and is still today far from established. Certain facts are known, *viz.*,

1. In an operating mill a seasoned charge, containing media of all sizes from that of the renewal or replacement size down to that which discharges automatically, normally produces better grinding than a new charge. It is inferred from this that a charge should be rationed to the mill feed, *i.e.*, that it should contain media of sizes best suited to each of the particle sizes to be ground. But Davis (*134 A 294*) and Coghill and deVaney (*CEG*), conclude from laboratory work that a range of ball sizes is unimportant or actually inferior. Usual practice is, however, to charge a new mill with a range of sizes, approximating on some basis or other, some seasoned load; to thereupon make periodic renewals, at various sizes dependent upon the character of the circulating load (see following para-

graph), until optimum grinding is attained; and thereafter to make required renewals at the maximum size.

Davis (*61 A 250*) reported experiments which he interpreted to indicate that the wear from a given ball is proportionate to its weight, *i.e.*, to d^3 (d = diameter). Bond's interpretation of Davis' data and later available material adopts the relation wear $\propto d^{2.3}$ (*153 A 373*). Prentice (*43 JCM 99*) reported an exhaustive series of wear tests in a 2 1/2×1 1/2-ft. cylindrical ball mill, with smooth liners, run at cascading speeds on Rand ore, but not with truly seasoned tumbling charges, nor with charges homogeneous in metallic character. His results indicated wear to be proportional to d^2. He cites sizings of seasoned loads from large Rand mills, operated cascading, that certainly fall much nearer to the predictions of the d^2 than to the d^3 rule; his citations are supported by those of White and of Clemmes in discussions of his paper. Prentice points out that the HOLLINGER sizing (*HS*), there interpreted as supporting the Davis rule, actually supports the d^2 rule.

From the mechanics of ball tumbling, established by Haultain and Dyer (Art. 2), it certainly follows that, in a cascading load, the superincumbent weight on the rubbing surfaces is independent of the diameter of the balls composing the tumbling mass, and is limited at any instant principally to the ball-to-ball and ball-to-liner near-contact areas in which grinding is being done, from which it follows that the wear on an individual ball is statistically proportionate to the extent of its surface, *i.e.*, to d^2. When a mill is run cataracting, however, the balls wear not only as in a cascading load, but also at the impact near-contact areas with the liner on the rising breast and with the balls at the surface of the toe. Here the forces prevailing at impact are proportional to mass × velocity of the cataracting balls, *i.e.*, to $d^3 \times d^{1/2}$. The combined wears in a cataracting load must, therefore, lie somewhere between d^2 and $d^{3.5}$, approaching one or the other limit the more closely according to the approach to critical speed. Davis' tests were, presumably, judging from the then-prevailing practice and the balance of his paper, run at cataracting speeds. Bond's data correspond to an integration of modern practice in which the proportion of the load which cataracts is relatively small.

Davis postulated that, once the distribution in the seasoned load is determined, it can be obtained by proportioning the new charge according to the equation $W = (d_1^3 - d_2^3)/d_0^3$ where W = decimal fraction by weight of desired size of ball in charge; d_1 and d_2 are the upper and lower limits of the desired size interval, and d_0 is the diameter of the renewal ball, and thereafter renewing with balls of the maximum size. The formula has been verified in practice by HOLLINGER (*HS*) and LAKE SHORE (*LSS*). For application of the Bond relation see Paragraph 4 below.

2. A coarse feed requires larger media than a finer feed. This is ordinarily explained either on the ground that large feed particles require heavier impacts, or that media of larger diameter are necessary to effect nip. It is true that if a circulating load tends to build up in the coarse end, the condition can be more or less corrected by increasing the size of renewal media (or increasing speed), while if there is a build-up in the near-finished sizes, charging of smaller renewal media is normally an effective remedy.

On the basis of the relationship thus indicated, Coghill and deVaney propose the equation $D^2 = Kd$ to determine optimum ball size for grinding a short-range feed through a given limiting screen, where D = diameter of ball and d of the coarser feed particles, both in inches, and K is a constant depending upon the grindability of the material (Art. 14) and equal to 55 for chert (very hard) and 35 for dolomite (soft medium).

Practice shows no consistent relationship between size of medium and limiting feed size. For 50 ball mills the ratio of renewal-ball diameter to nominal limiting feed size ranged from 2.5 to 130, averaging 20, with the mean at 14; range in nip angle, on the basis of balls in contact, was 14 to 89°, average 48°, mean 43°. For 21 rod mills the diameter ratios were: range 1.5 to 46, average 11, mean 4; nip angle, range 24 to 106°, average 62°, mean 47°. Since practice normally represents a distillate of long-time small-step experimentation, the width of the ranges reported and spreads between averages and means indicate a definite lack of dependence in practice between maximum diameter of tumbling body and limiting-feed size. In general, however, renewal rods in primary mills are 3 to 4-in. diameter, and 1 1/2 to 2-in. in secondary; in primary ball mills renewals are at 2 1/2 to 5-in. in diameter; in normal secondary service 1 1/2 to 2-in., and in ultra-fine secondary and tertiary circuits as small as 1 or even 3/4-in. Johnson (*D, 153 A 333*) stated that in the latest large-scale test work, *viz.*, at MORENCI (1938–1940), it was found that 2 1/2-in. balls were large enough for 3/4-in. feed in 10-ft. mills. In general, the largest ball should be the smallest that will do the work, because both ball and liner wear increase with ball diameter. Pebble renewals in fine-grinding are normally at about 3-in. but when mine rock is used for the tumbling load it may be charged as coarse as 8-in. For commercial sizes of pebbles see Table 21.

3. The smaller the *mog* the smaller the optimum diameter of medium. This relationship is attributed to the fact that fine product is produced most effectively by rubbing, whence maximum capacity to fine sizes is attained by maximum rubbing surface, *i.e.*, with small balls. A practical limitation is imposed by the tendency of balls which are too small to "float" out of the mill, and by the high percentage of rejects when renewals are too small.

On the basis of this relationship the majority of operators ration ball charge primarily to the *mog* on some ground which may be rationalized statistically on the basis of nip angle at *mog* diameter. Curves showing approximate relationships between *mog* and nip angle for 50 ball mills and 21 rod mills are presented in Fig. 23. At LAKE SHORE (*LSS*) decrease from 1 1/4-in. to 3/4-in. in the size of renewal

balls in 5×16-ft. tube mills grinding to 56-μ *mog* increased capacity of the mills 23.5% with an increase in ball cost of 7.1%. The same increase accompanied the same change in laboratory mills grinding the same feed. (See Table 11.) These experimenters found further that the curve of performance, although relatively flat over the range of 0.8 to 1.1 times the optimum diameter, fell rapidly outside these limits. At HOLLINGER (*HS*) decrease in renewal size of balls from 3-in. to 2 1/2-in. with <3/8-in. feed and 48 *mog* increased capacity of a 6 1/2×14 1/2-ft. mill from 1,430 tons new feed per day to 1,507 or 5.4%, with no other change in conditions or results (see Table 5).

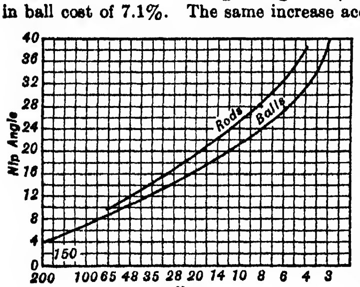

FIG. 23. Nip angle (closed basis) *vs.* *mog* in tumbling-mill practice.

4. The harder the ore the larger the ball needed, all other things being equal. Recognition of this fact is reflected in the values of the constant in the Coghill and deVaney equation above. Bond (see below) reports a similar relationship.

Rationing of tumbling charge as practiced is described in paragraph **1** above. Bond (*153 A 373*) has proposed an analytical method, based on a modification of the relationship of ball wear to ball weight established by Davis (p. 27).

Symbols:

A = Nip angle for two balls of the same diameter in contact.

B = Optimum ball-size differential = minimum difference in the Stadler number of an ore particle and that of the ball necessary to break it efficiently. The value of B for a 6-ft. mill wet-grinding ore of medium hardness is approximately 4, for an 18-in. laboratory mill 7, and for a 12-in. laboratory mill 8; for hard ores add 1 to the value for a medium ore.

b = Subscript = ball.

C = Area in sq. cm. within which two balls of diameter d_b in contact will nip a particle of diameter d_p.

F, D = Subscripts denoting renewal-ball and reject-ball diameters respectively. N_D is taken here = 55, or about 1/2-in. rejects.
d = Diameter in cm.
K_1 = A constant for a definite amount of grinding.
K_2 = A constant for the production of a specific amount of new surface area.
m = Slope of Gaudin distribution line (Sec. 19, Art. 19) for balls of equilibrium (= seasoned) charge.
N = Stadler number of sieve that just passes a ball of diameter indicated by subscript letter.
n = Stadler number (Sec. 19, Art. 19).
O = Subscript = optimum.
P_F = Theoretical per cent. by weight of equilibrium charge that would be indicated on screen N_F, if the distribution line were extended to that ordinate.
P_n = Per cent. by weight of equilibrium charge retained on a screen with Stadler number n and not retained on one with number $n + 1$.
p = Subscript = particle.
S = Surface area in sq. meters per 100 cc. of metal in ball charge.
W = Grams weight loss of any ball for a definite amount of grinding.
W_T = Grams weight loss per ton of balls for the production of a specific amount of new surface area.

Equations:

$$n_{bd} = 6.64 (\log d + 8.07) + 1 \tag{1}$$

$$\log W = 0.345n + K_1 \tag{2}$$

$$P_F = \frac{79.4}{0.672 - \dfrac{1}{\text{antilog } [0.345(N_F - 55)]}} \tag{3}$$

$$\log P_n = 0.345(n - N_F) + \log P_F \tag{4}$$

$$S = \frac{157{,}800 P_F}{2^{\frac{1}{2}(N_F - 1)}} \{0.799 - \text{antilog } [0.194(55 - N_F)]\} \tag{5}$$

$$\log W_T = K_2 - 0.107n \tag{6}$$

$$d_{bo} = 2^{B/2} d_p \tag{7}$$

$$B = 6.64 \log \frac{d_b}{d_p} \tag{8}$$

$$C = \frac{\pi d_b d_p}{2} \tag{9}$$

$$C_o = \frac{\pi d_b^2}{2^{B/2} + 1} \tag{10}$$

$$\cos A = \frac{1}{1 + \dfrac{1}{2^{B/2}}} \tag{11}$$

Example. To determine initial and equilibrium ball charges for grinding <1 1/2-in. feed to 65 *mog* in a 7-ft. mill at 20 r.p.m. in closed circuit with a classifier.

A summary of the calculated data is given in Table 12. Screen analysis of the mill feed (new plus circulating) with Stadler numbers of the sizing screens are given in columns 1 to 3. Stadler numbers of limiting screens for balls are given in column 4. The basis for their magnitude is that test has shown that $B = 4$, whence $N = n_p + 4$. The factors in column 5 are based on an analysis (see original paper) indicating that optimum distribution of sizes N in the ball charge is attained when the cumulative per cent. of a given size of ball in the charge is obtained by multiplying the cumulative per cent. of the corresponding size ($n_p = N - B$) in the composite feed by the factor. The factors are obtained by making the factor for the largest ball = 1 and deriving each succeeding factor by multiplying the preceding factor by 1.29. Cumulative size distribution of the optimum ball charge (column 6) is then obtained by multiplying the values of column 3 by those of column 4 until the indicated percentage exceeds 100. The daily feed that it is necessary to make in order to attain an equilibrium charge that will approximate the optimum charge is obtained by dividing the percentage of the largest ball in the optimum charge (22% of 5-in. in Table 12) by the percentage of this size found in an equilibrium charge attained by constant feed of this largest size only. Values for such charges are given in Table 13. For 5-in. renewal size the value is 31.7. Hence 69.4% of the renewals should be 5-in. These will wear to equilibrium percentages of the total load in the present mill as shown in column 7, Table 12, derived by multiplying the tabular values for 5-in. balls in Table 13 by 0.694. The excesses in column 7 above the values of column 6 cannot be remedied. Deficit, as for sizes 59 and finer, are made up by addition of smaller balls. In the instant case the deficit is taken up by adding 2-in. balls, applying the multiplier 0.306 (= 1 − 0.694) to the equilibrium values for 2-in. balls (Table 13), giving the values in column 8. Column 9 is the summation of columns 6 and 7, and is supposed to represent the seasoned charge that would result from a daily feed of 5- and 2-in. balls in the proportions taken in Table 12. The initial ball charge, made up from standard sizes, which most closely approximates the equilibrium charge of column 9, is given in columns 10 and 11.

The charge is determined by plotting the cumulative per cent. weights of column 9 against the values of N in column 4, smoothing the best curve through the points, sliding the scale of ordinates one-half unit to the right, and reading cumulative weights corresponding to the values of N for the commercial sizes of balls, as taken from Table 13, against the shifted scale, except that the value for the coarsest size is taken as one-half the value read, and the remaining half is added to the weight of the second size.

Equilibrium load ***vs.*** **a seasoned load.** Fig. 24 presents a comparison between a sizing test on a seasoned charge of forged-steel balls after 13 mo. operation in a 6 1/2×14 1/2-ft. mill at HOLLINGER (*HS*) with 3-in. renewals, and an equilibrium load with 3-in. renewals calculated by the Bond method. The agreement is so close as to constitute strong evidence of the general validity of the method, although on the basis of the one comparison available, somewhat more rapid wear of the largest balls and a compensating slower wear of the smaller sizes is indicated in practice.

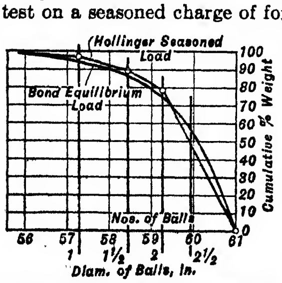

FIG. 24. Comparison of equilibrium and seasoned ball loads.

Barker and Lewis (*153 A 333*) carried out an extensive program on ball rationing in a 2,500-ton 4-mill test section at NEW CORNELIA, with the balance of the mill, comprising 7 similar sections, for reference. Their conclusion was that definite increases in capacity and efficiency (tons to desired *mog* per hp-hr.) are obtainable by rationing make-up balls to produce and maintain a seasoned charge suited to the composite mill feed. If make-up is

at maximum ball size only, the seasoned charge shows a percentage-weight distribution that decreases gradually from coarsest to finest. Thus with 3-in. additions the seasoned charge analyzed: 2 1/2-in., 54.8%; 2 1/2~2, 25.5%; 2~1 1/2, 9.6%; 1 1/2~1, 7.7%; <1-in., 2.4%. Such a charge produces crowding in the finer sand sizes on a once-through operation, and the crowding is aggravated by closing the circuit. By adding smaller make-up balls with the large, the distribution in the equilibrium load is changed markedly, the character and magnitude of the changes depending upon the ration. Thus the seasoned load for a make-up ration of 70% @ 2-in. and 30% @ 3-in. balls was: 20.1% >2 1/2-in.; 10.3%, 2 1/2~2; 42.7%, 2~1 1/2; 18.7%, 1 1/2~1; 8.2% <1-in. This ration decreased but did not wholly eliminate crowding in the fine-sand sizes in mill discharge. The evidence was that addition of some yet smaller balls to the make-up ration would have produced a yet more uniform mill discharge, with concomitant further increases in mill capacity and efficiency, but the estimated resultant higher ball consumption, due to increased percentage rejections by the mill, led to the conclusion (without experimental confirmation) that such increase would not be economical. The broad conclusion was that large balls grind the coarser feed particles; medium-size, the intermediate; and small, the fine. Ball wear, starting from a ration of large balls only, will not produce a seasoned load best fitted to the seasoned composite ore feed to the mill. Proper rationing also increases classifier efficiency.

At Consolidated Mining & Smelting Co. (*PC*) extensive tests (18 mo.) were carried on to determine the effects of ball size on capacity, production of <200-m., and efficiency, with respect both to particular grinding mills and to the 3-stage grinding operation considered as a unit. Optimum production of <48-m. (0.138 t.p.hp-hr.) and of <200-m. (0.102 t.p.hp-hr.) occurred in the primary mills (10-ft. × 48-in. Hardinge, at 16.1 r.p.m., 64% of critical, taking 55 t.p.h. of <1/2-in. feed, operating at 64% solids) when replacements comprised a mixture of 3-, 2-, and 1 3/8-in. balls. Elimination of either or both 3-in. and 1 3/8-in. balls from the ration decreased the tons <200-m. per hp-hr. In the secondary mills (10-ft. × 48-in. Hardinge, operating at 80% solids, taking a composite load of 205 t.p.h. of <28-m. classifier sands), change from 2-in. replacements to 1 3/8-in., coupled with nonremoval of 1-in. balls, increased the production of <200-m. per hp-hr. by 44.5%, and permitted increase of 42 t.p.h. new feed to the grinding plant without change in over-all grind or in grinding or classifier equipment. In the retreatment grinding (8-ft. × 48-in. Hardinge mills with Akins and bowl classifiers, taking <100-m. feed), change in ball size from 1 3/8-in. replacements to 3/4-in., and in slope and speed of the classifiers were made simultaneously. The result was an increase of 31% in production of <200-m. per hp-hr., which was attributed to the combined effects of ball size and classifier slopes (change in classifier speed thought to have been without effect). Performance of the 13 mills installed (see Sec. 2, Fig. 116) in March 1942, milling 8,200 t.p.d., follows:

Stage	Hp. consumed	Tons 200-m. produced		Ball consumption, lb. per ton				
		Per day	Per hp-hr.	3/4-in.	1 3/8-in.	2-in.	3-in.	Total
Primary *a*	1,440	2,775	0.080	....	....	0.383	0.094	0.477

New rod load is usually patterned on an old load that has worked down to a distribution which gives optimum grinding. Table 14 gives size analysis of the load removed from a Flat River mill.

A distribution in a mill taking <3/4-in. feed in open circuit was: 4-in., 12.7% of the number of rods and 34.7% of the weight of charge; 3-in., 24.8 and 36.9% respectively; 2-in., 28.1 and 18.3; 1 1/2-in., 20.4 and 7.6; 1-in., 14.0 and 2.4.

Since the distribution varies somewhat with different ores, reduction ratios, and feed rates, a rough rule for new loads for secondary-crushing service is 1/8 of total number at 4-in., 1/4 at 3-in., and 5/8 at 2-in. and 1 1/2-in. about equally distributed. For finer feeds in primary grinding service a new load of about equal weights of 2-in. and 1 1/2-in. rods gives a fair balance between good grinding in the shake-down period and rod life.

Volume of charge for maximum capacity in any mill is that which will draw the most power (Art. 15). In general this amounts to a struck volume of about 50% of mill volume, *i.e.*, a load to the axis with the mill at rest. Normal operating loads range from this down to 40%.

At MAGMA (*IC 6757*) load is changed according to capacity requirements. At CANANEA (*ibid.*) increase in charge from 9 to 15 tons, corresponding to 31 and 52% of mill volume, respectively, caused 67% increase in production of <48-m. with only 27% increase in power draft. At LAKE SHORE (*LSS*) maximum capacity of a 6×16-ft. grate mill was with a 50% load; at 43% load the capacity was down 19% and at 60% load it was off 15%. In a high-discharge mill increase in load from 45 to 50% by use of an annulus in the discharge trunnion increased capacity 4.4% with a 4% increase in hp. (*44 CIMM 380*). At HOLLINGER (Table 2) tests 3 to 5 at the best speed (Art. 2) show better than 10% advantage in capacity for 50% load as against either a larger or smaller load, with efficiency favoring the smaller load slightly.

Table 14. Analysis of rod charge from a Flat River mill (*IC 6658*)

Total	555	50,607	100.0	525	56,772	100.0

a Broken; 2 to 7 ft. long.

Charge volume and speed are interdependent in that with low volume and high speed power draft is the same and capacity corresponds. Larger media are required with smaller loads to maintain tonnage. A small charge with high discharge reduces capacity markedly; it is restored to some extent by lowering discharge, or diluting the pulp. ROD CHARGE normally is 40 ± 5% and averages lower than ball charges.

Weight of charge per cu. ft. of struck volume is, of course, dependent on the shape of the media and the type of packing. Gow (*134 J 203*) determined by experiments with lead shot that the percentage of voids in shake-down random packing was 38, comprising a rough average between 30% in tetrahedral packing and 48% in cubic. The voids in shake-down packing are substantially the same irrespective of whether the balls are of the same size, of nearly the same sizes, or of a size distribution corresponding to a seasoned load, but they decrease if part of the load is of subinterstitial size. The weight of steel balls corresponding to 38% voids is 300 lb. per cu. ft.

No similar determination has been made of the weight of rods. If, however, the assumption is made they likewise assume a shake-down packing that is the substantial mean of hexagonal and rectangular, and that the normal range in diameter of a seasoned load does not change the voids substantially, the weight per cu. ft. of struck volume is between 400 and 425 lb.

Coghill and deVaney (*CEG*) state that 72 lb. of <6-m. pulp filled the interstices of an 800-lb. ball load at rest and that 39 lb. of the same material filled a 1,020-lb. rod load. On the basis of these figures the weight of the rods is 390 lb. per cu. ft. of struck volume.

Material of tumbling bodies is important from the standpoint of specific gravity, hardness, toughness, and delivered price.

Specific gravity. Mill capacity increases materially, although not quite directly, with increase in superincumbent load; also, so far as the coarser part of the feed is concerned, with increase in momentum of the falling bodies. Both of these quantities increase directly with specific gravity of the medium, all other things being constant. It follows that the capacity of a given mill will be greatly increased with a change from a pebble to a ball charge. There is, of course, marked increase in power draft also, if the same struck volumes of media are employed, and a smaller increase for the same weight of media. Consequently efficiency may not change materially. Data covering comparative performances of mills with ball and pebble loadings are given in Tables 15 to 19. Similar performances have been reported for changes from pebbles to balls in RAND tube mills. At UTAH substitution of balls for pebbles in 7×10-ft. mills increased capacity to flotation size threefold. Pebbles should be larger than balls for comparative reductions of coarse feeds.

At COPPER RANGE an 8-ft. × 30-in. mill carrying 10,000 lb. of pebbles ground 65 tons per 24 hr. Change to 9,000 lb. of balls raised the capacity to 150 tons without substantial change in screen test of product. At MIAMI COPPER Co. change in load of an 8-ft. × 22-in. conical mill from 8,000 lb. of pebbles to 15,000 lb. of balls, open-circuit grinding, increased capacity from 178 to 300 tons per 24 hr. and produced a slightly finer product at a slightly lower rate per hp-hr. Pebble consumption was 1.14 lb. per ton and consumption of 2-in. manganoid balls 1.21 lb. per ton (see Table 16). Closing the circuit on the ball mill with a rake classifier gave a yet finer product at substantially the same power consumption. Comparative costs are given in Table 17. Power for ball milling cost 8.2% more than for pebble-mill grinding; grinding medium, 251% more and lining 152% more; labor cost was

about the same for both. At the same plant, changing the grinding load in an 8-ft. × 66-in. conical mill from pebbles to balls increased average capacity from 250 to 330 tons per 24 hr. but doubled the per-ton power consumption and more than doubled the cost per ton for regrinding (see Tables 18 and 19). On the other hand, the product reground in the ball mill contained 97.6% <65-m. material while that from the pebble mill contained only 48.2% and was unsuitable for flotation feed. Further, the capacity of a mill section with a ball regrinding mill was 822 tons per 24 hr. as against 714 tons with a pebble mill. Increased recovery and tonnage on the ball-mill section more than compensated for increased regrinding costs. CALUMET & HECLA continued to use pebble mills in regrinding until war shut off the supply in 1939. Their stand is clearly justified by Benedict's statement (*117 J 282*) that on the hard conglomerate ore pebble wear is 4 to 5 lb. per ton and ball wear almost as great; pebbles cost $0.0075 per lb. and balls $0.035 per lb.; and the difference in cost on this score alone is $0.10 per ton in favor of pebbles. At WRIGHT-HARGREAVES (*115 J 884*) there was an actual saving in power attendant upon a change from pebbles to balls. Two 5×16-ft. cylindrical pebble mills with El Oro liners ground ball-mill product to 60% <200-m. at the rate of 125 to 150 tons per 24 hr. and consumed 70 to 75 hp. (=0.045 to 0.050 tons <200-m. per hp-hr.) Change to ball loads (20,000 lb. each mill) increased the daily capacity to 200 to 260 tons containing 80 to 85% <200-m. and power consumption at 28 r.p.m. was 90 to 100 hp. (=0.078 to 0.087 ton <200-m. per hp-hr.).

Composition of balls and rods. The usual materials for balls are chilled cast iron and forged steel, for rods high-carbon steel, all more or less alloyed. Data are insufficient to support any general statements as to best composition for either. Summaries of a few actual analyses are given in Table 20. Usual procedure in ball purchases is to test a

c A leading manufacturer of grinding equipment has found the following specification generally satisfactory.
d This rod has given good service under some conditions.
e See also Table 21*A*.

locally cast product against forged alloy ball and base future use on the economic results. Practice is about equally divided for secondary mills, but forged steel predominates in primaries, especially when the balls exceed 3-in. diameter, when mill diameter exceeds 6 ft., and when mills are run at cataracting speeds.

Lawler (*112 J 5*) warns that most locally made balls from assorted scrap of unknown composition have a carbon content ranging from 0.2 to 1% when the proper limits are 0.6 to 1%, that the chrome in chrome-steel balls ranges from nil to 0.05%, and that balls from most small forges will vary greatly from shipment to shipment.

RODS should be hot-rolled and machine-straightened. Mild-steel rods are unsuitable for the reason that they bend and kink after wearing down to a certain minimum diameter and snarl up the whole rod load. The hardened-steel rods break up when they wear down and are removed at about 1-in. or left in and eventually discharged in small pieces. Experience at TENNESSEE indicated emphatically that removal of 1-in. and smaller rods definitely increased efficiency. Consultation with an independent metallurgist is recommended both as to the most promising alloy ball available and as to composition, control, and heat-treatment of cast balls.

An inkling of the service to be expected from such a consultant may be gained from the following excerpt from *26 #8 MCJ 35*. At a mine with a hard ore (7.25 Mohs) and with high transportation

charges, high-carbon copper-molybdenum forged-steel balls were tried. The molybdenum content permitted a higher carbon content (hence increased hardness) without brittleness, and caused deeper penetration of surface hardening (1 1/2 in. in a 4-in. ball as against 7/32 in. for the usual forged ball). The copper contributed corrosion resistance. Brinell readings were: 720 at surface (*vs.* 640 for usual ball); 450 at center (*vs.* 360 usual); hence average volumetric hardness for a 4-in. ball was 660 (*vs.* 390). A 4-in. Cu-Mo ball was 98% "fully hard" *vs.* 29% for ordinary heat-treated forged steel. Grain size was watched carefully during manufacture and the balls were heat-treated only after pilot batches had been put through.

Hardness of tumbling body increases capacity and efficiency and decreases wear. The effects are much more pronounced with hard ore than with soft.

Coghill and deVaney (*CEG*) report an increase of 30% in efficiency on changing from rods made of old boiler tube (annealed by use) stuffed to a specific gravity of 7.3 to steel rods (sp. gr. 7.7), although the change in efficiency with the boiler tubes on change of specific gravity of stuffing had been relatively small. They also tested Nihard balls (2.5–6% Ni, 0.5–1.5 Cr, 548 Brinell) as against annealed cast-iron balls (150 Brinell). The Nihard ground 21% more chert per unit of power than the soft iron; the difference was not so marked with dolomite. Usual hardness range for cast-iron balls is 400 to 500 Brinell; forged balls are normally softer as forged but may be tempered as high as 600 to 625 Brinell for the smaller sizes and 500 to 550 for the larger. Hardness of Lorain forged-steel balls (Carnegie-Illinois Steel Corp. *PC*) is 600 to 675 Brinell for balls up to 3/4-in. diam., and 550 to 650 for the larger balls. Rose (*134 A 361*) points out that forged-steel balls of 475 to 525 Brinell, which are rust-resistant, gave the best wear (@ 1 lb. per ton) at Copper Range and Homestake. At Lake Shore (*LSS*) an unknown considerable drop in hardnes of balls resulted, over a period of 6 mo., in a material falling-off in grinding performance, due, probably, both to the decrease in grinding effect of the softer balls and to a gradual decrease in volume of tumbling charge, the daily quota of balls having been based on wear of harder balls. Coghill and deVaney report sceleroscope hardnesses of pebbles as follows: Flint, 94; jasperoid, 102; artificial sillimanite, 82.

Toughness of tumbling body determines the amount of breaking thereof, with consequent early rejection and loss of use. Toughness has always been an important factor in choice of pebbles, but alloying and heat-treating of balls for toughness is a comparatively recent practice.

At Loreto (*112 A 728*) the consumption of 5-in. forged-steel balls in 8×6- and 6×12-ft. primary mills decreased from an average of 1.8 to an average of 1.45 lb. per ton owing to heat-treatment; in 6×10- and 5×10-ft. secondary mills the corresponding figures were 2.75 and 1.61.

Heat-treated forged chrome-steel balls of relatively high carbon content (0.6–1%) and containing 0.5–1% Mn are tough and reasonably hard. Toughness is of primary importance when there is considerable impact grinding, *i.e.*, with large balls, high speeds or rough liners, or mills of large diameter.

In a 5×10-ft. open-end primary ball mill at Mammoth (*153 A 396*) running at 80% of critical, reducing from 1/2-in. to 8-m., 4-in. cast-iron balls were substituted for 4-in. forged-steel for a few months but breakage of large balls reduced capacity to a point where over-all costs were higher.

Pebbles have a specific and particular advantage over metal grinding media when contamination by iron must be prevented, as in grinding some industrial minerals, *e.g.*, talc, lithopone, chalk, feldspar, and quartz. They also had for many years a geographical freight differential in South Africa, where balls had to be imported, and hard rock that made a usable pebblelike grinding medium was a part of the ore mined. Otherwise, where competition between pebbles and balls has been direct, balls have almost invariably been chosen, either because of a direct advantage in operating cost (p. 35), or because, although operating costs were close, the higher tonnages possible with balls made profits greater therewith. In a few special instances, of which Calumet & Hecla is best known, the ore (conglomerate) is so hard that ball wear was 3 1/2 to 4 lb. per ton at 3 1/2¢ per lb. (1930) *vs.* 5 lb. Danish pebbles at 3/4¢ per lb. This cost differential, particularly when taken with the fact that the grinding installation was more than adequate for the declining ore supply, made pebbles the inescapable choice. Capacity of an 8-ft.×72-in. conical pebble mill from 3/16-in.~20-m. feed to 35 *mog* was 110 tons per 24 hr. at a cost (1929; *IC 6357*) of 12.6¢ per ton, of which more than half was for power (19.6 hp-hr. per ton).

Table 21. Trade numbers and sizes of pebbles

Number	Size, in. Min.	Size, in. Max.

7	4 3/4 to 5 1/2	7 to 7 7/8

Supply. Desirable pebble is tough, hard, heavy, as nearly spherical as possible, resistant to chemical reaction with the material being ground, of such composition that its dust is not harmful in the ground product, and cheap. The best pebbles came from the Danish coast; an inferior quality from France; both flint. Newfoundland pebble, less satisfactory than either, is graywacke. A domestic pebble comprising a mixture of tuff, porphyry, and granite from San Diego Co., Calif., has had considerable local use for grinding cement clinker (*IC 7139*). The same bulletin lists possible domestic sources and dealers. Local hard rock has rarely proved practically useful; wear is almost invariably excessive on account

Q Quenched from about 1,000° C. in warm water.
U Unquenched.

of high breakage, and efficiency is low owing to softness as compared with good natural pebble and to the tendency to form flat shapes which decrease rubbing. The outstanding exception was the RAND. At the WEST END mill (*110 P 139*) artificially rounded (tumbled) locally mined flint was consumed in a mill with smooth-iron lining in the proportion of 1.05 to 1 of Danish pebbles in a mill with Komata lining, while the cost per ton ground was only 4/7 of the cost of imported pebbles. Local pebbles wore flat and occasionally stuck in the grate. At HEDLEY GOLD MINING CO. (*114 J 1057*) Danish pebbles at $33 per ton delivered cost, on the average, $2,600 per month; substitution of local pebbles at $4 per ton cut the cost to $600 per month.

Pebble is sold by numbers designating size; the size range corresponding to different numbers varies somewhat according to the dealer; usual range is given in Table 21. Pebbles for a given service should usually be larger than balls because of lower specific gravity, which reduces striking power and increases the size of rejects; use of large pebble also reduces the percentage of reject.

Testing tube-mill pebbles. A large part of pebble consumption is due to chipping, which occurs principally at the feed end of the mill. Allen (*105 J 1033; 124 P 405*) contends that toughness is the important property of suitable pebble material and that a tough soft rock may be superior to a hard but brittle flint. He suggests testing pebbles for hardness, toughness, and abrasion by the methods practiced for testing road material (Sec. 3, Art. 41). Pebbles tend to wear flat with smooth liners but to maintain more nearly original rounded shapes with ribbed liners.

Use of pebbles in ore milling today is largely confined to the Rand. For more details on such materials see *Ed. 1, pp. 430 to 433.* King and Clemes (*46 IMM 600*) state that primary ball milling on Rand costs about 2¢ per ton more than when using reef pebble, but that tonnage ground is markedly higher.

Wear of balls depends upon the material of the ball and the method of manufacture; the material being ground; mill diameter, speed, and height of discharge; feed rate, pulp density, liner surface, and ball diameter.

Material of the ball and the method of manufacture determine hardness, toughness and corrosion resistance. CORROSION both by acids introduced with the pulp and by oxygen is an important element in steel consumption. Acidic corrosion is minimized when lime is added to ball-mill feeds; alloying for hardness and toughness ordinarily increases rust resistance also. It should be borne in mind that rusting may be proceeding actively in a mill despite that balls and liner in the operating mill are visually clean and bright. The reduction in oxygen content in high-sulphide pulps protects the steel in such circuits.

Results of tests by Prentice (*43 JCM 99*) in a 2 1/2×1 1/2-ft. cylindrical mill, run at cascading speeds with smooth liners, grinding Rand ore (44% >48-m.), are given in Table 21*A*. The data on heat treatment are so scanty, however, and the indicated treatment was so inadequate, both in itself and in its blanket application, as to narrow the value of the data materially from the standpoint of correlation of analysis with consumption.

Material being ground affects wear from the standpoints of size, abrasiveness, and chemical composition. All other things being equal, the intermediate sand sizes (14- to 35-m.) appear to cause maximum consumption, both by abrading more, and because they key the load higher on the rising breast of the mill. Coarse feed decreases ball-to-ball contact; very fine feeds usually result in sufficient very fine material in the mill to cushion and lubricate the load to an appreciable extent. As a consequence, unless there is excessive breakage, consumption in primary mills is less than in secondary. Ball size (less surface per ton) may play some part in this, and ball material (forged-steel primary, cast secondary) is the cause in many cases. Difference in crushing resistance and abrasiveness between primary and secondary feeds is a common cause of difference in steel consumption. In primary grinding the major part of the work consists in breaking grain from grain and in breaking the softer grains. Much of the softer material is removed finished ahead of the secondary circuit, leaving to the latter the tough and generally hard and abrasive material to finish. Pulp constituents that introduce iron-reactive compounds are discussed in the preceding paragraph.

Mill diameter and speed determine the impact loads and the pressures between media (Art. 3). Wear increases, of course, with increase in these quantities. At LAKE SHORE (*LSS*) extensive tests indicated that wear is proportional to $D^{2.6}$ (D = mill diameter), all other conditions being constant.

Height of discharge determines, with feed rate, the amount of interstitial pulp; pulp density and size of grain determine its consistency. The more interstitial material and the greater its plastic resistance, the less the wear per pass, but consequent increase in circulating load with concomitant increase in number of passes to effect a given amount of finished grinding may eat up much or all of the saving due to these causes. Table 22 shows ball consumption in the 3 mills reported to be directly proportional to the lowness of the discharge.

Table 22. Height of discharge *vs.* ball wear at a Rand mill (*After King and Clemes, 46 IMM 601*)

Mill, diam. × length, ft.	Diam. of discharge, in.	Ball consumption, lb. per ton of new feed	Tons <200-m. produced per hp-hr.
6 1/2×9	41	2.5	0.035
6 1/2×9	52	2.7	0.035
9×10	60	2.2	0.040

Liner which produces the most activity of the load will, in general, produce the most wear. The effect of liner surface is fully presented in the following data from LAKE SHORE (*LSS*).

Careful and long-continued tests (3 to 25 mo.) with ball addition into each mill weighed, made, recorded and reported to the test staff daily by one man, demonstrated that (ball) wear is a function of liner surface and hardness, mill speed, and height of discharge. Thus wear of 3/4-in. cast balls (Brinell 477 to 514) with Cobalt pocket liners and pockets empty was 92% of that with full pockets; with Cobalt and clover-leaf pocket liners of the same hardness (495 Brinell), with full pockets the 3/4-in balls wore equally; the wear of 1 1/4-in. forged-steel balls (Brinell 575 to 625) was comparatively 98 with Nihard ripple liners (Brinell 683), 90 with Nihard smooth (Brinell 500 to 600), 78 with the same liner after it had worn to circumferential grooving, as against 100 with Cobalt pocket liner with full pockets. Similarly, wear of the 3/4-in. balls with smooth cast-iron liners (Brinell 418 to 460) was 96, and with grooved (Black grooving) liners of the same material 80, relative to the wear with Cobalt pocket liners (Brinell 495) with full pockets. Wear of the 1 1/4-in balls against a ripple liner of 290 Brinell was 92% of that against a ripple liner of 683 Brinell, all other things being equal. Wear of the 3/4-in. balls against empty Cobalt pocket liners (Brinell 495) was 97% as great at 27 r.p.m. as at 30 r.p.m., all other conditions being the same. Wear of both the 3/4- and 1 1/4-in. balls with the full Cobalt pockets was 72% as much in a high-discharge mill as in the same mill with low discharge.

Ball diameter affects consumption in two ways. Large balls at cataracting speeds tend to break small balls. On the other hand, in a mixed load large balls wear faster than small.

At SYLVANITE (*41 CIMM 284*), all other things being equal, ball wear with 4-in. forged-steel renewals was 2.76 lb. per ton as against 2.62 lb. with 3 1/2-in. balls; with mixed renewals (3 1/2-in., 70%; 4-in., 30%) total consumption was 2.67 lb., but consumption of 4-in. balls was at the rate of 1.86 lb. as against 1.83 lb. for the 3 1/2-in.

Shape of worn balls. Prentice's tests (*loc. cit.*) confirm the observations at HOLLINGER (*HS*) that balls with initial surface unevenness, such as a casting neck, surface pit, circumferential ridge, or the like, wear unevenly, and in such a way as to increase the initial departure from sphericity and to approach first a double-ended pyramid, then a tetrahedron, and finally a shallow cylinder with dished ends. All of the evidence is that the irregularly shaped tumbling bodies (in a cascading load) settle down into the interstitial spaces between the larger balls, thus excluding and protecting pulp to a considerable extent. This would tend to support the practice followed in some plants of screening out the small balls and fragments periodically, particularly from primary-mill loads.

Wear of forged-steel balls in primary service ranges in general between 1.0 and 1.5 lb. per ton of new feed, with an occasional figure as low as 0.75 lb. or as high as 4.5. The exceptionally high figures correspond to one-stage grinding of coarse feeds to fine *mogs*, *e.g.*, <1 1/2-in. to 100 or 150 *mog*. In secondary service reported consumptions range from 2.0 to 3.5 lb., but the number of reports is small and the higher figures are for exceptionally hard service. Consumption of cast-iron in primary service ranges from 1.0 to 3.0 lb., but such use is usually confined to ores that grind easily; the usual range in secondary service is 1 to 2 lb.

Size of feed and amount of recirculation had no effect on ball wear at LAKE SHORE over the range of feed size from 55% >65-m. to 55% >200-m. and of circulating load from 20% to 300% (*LSS*).

Consumption of rods varies widely. Disregarding exceptionally high and exceptionally low values, the range is from 0.2 lb. per ton for soft ore to about 2 lb. for hard, averaging close to 1 lb. for 20 mills.

At BALMAT (*IC 6674*) consumption was reduced about 0.4 lb. per ton by routing new feed directly to the mill instead of to the classifier.

Pebble consumption. When mine rock is used, the consumption ranges from 15 to 200 lb. per ton of feed. With flint pebbles the average is about 2 lb. per ton and the usual range from 0.5 to 8.0. Hard ore, naturally, causes greater consumption than soft. Coarse feed consumes more than fine.

At WEST END mill (*110 P 139*) feed was battery product through 0.27- and 0.19-in. screens, hard but not tough quartz. Mill product was 80% <200-m. Pebble consumption averaged 7.1 lb. per ton; range was from 4.8 lb. with the finer feed and Danish pebbles to 8.7 lb. with coarse feed and French pebbles. Consumption at three other mills in the district taking finer feed and finishing to the same size was 4.2, 4.4, and 4.7 lb. per ton.

Fine grinding consumes more pebbles than coarse. Consumption in closed-circuit grinding is greater than in open-circuit work, as a general thing, but it is probable that this is due to the fact that the product of closed-circuit work is generally the finer. Ribbed liners cause higher pebble consumption than smooth on account of the greater tumbling that they produce. High moisture content causes high pebble consumption. Consumption per ton of initial feed is lower the greater the circulating load.

Ball wear *vs.* power consumption. DeVaney and Coghill (*138 J 337*) found by laboratory tests that ball wear per unit of power input is independent of mill speeds through the range from 26 to 80% of critical, and of ball sizes, provided the load is constant. They examined a considerable number of operating records and found that the wear when expressed in pounds per hp-hr. was less fluctuating than when expressed in pounds per ton

crushed, but that it was far from constant. For steel balls the average of 54 mills was 0.15 lb. per net hp-hr. with a range from 0.054 lb. to 0.29 lb. Rod wear averaged 0.2 lb. per net hp-hr.

At Government Gold Mining Areas (*37 JCM 108*) grinding pyritic flotation concentrate to 90% <325-m., the consumption of tumbling medium (drill slugs) was 13.5 lb. per ton ground.

Maintenance of charge volume is difficult to insure. Usual procedure is to charge a fixed weight per day based on average ball wear. At some plants additions are based on power readings, but in this practice account must be taken of the effect of liner wear. Daily charging is better than at longer intervals, as it maintains more even operation.

Ball-casting machine as built locally for local casting is described with working drawings by Huttl (*127 J 806*).

7. ROD MILLS

Description. The rod mill has a cylindrical shell (Art. 3), the length of which ranges from 1 1/3 to 3 times the diameter. It is made both in overflow (Fig. 25) and open-end

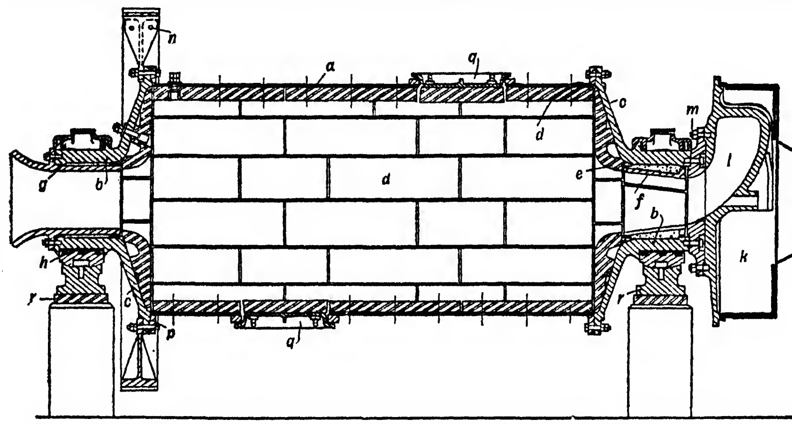

Fig. 25. Trunnion-type rod mill (*after Allis-Chalmers Mfg. Co.*).

(Fig. 26) types. Heads and end liners are usually such as to present a plane inner surface, but slightly coned ends can also be used. Feed trunnion is made as short as possible to accommodate coarse feeds. Rods are a few inches shorter than the inside length; usual range of rod diameters is 1 1/2 to 3 1/2 or 4 in. Load is limited to 40 to 45% of mill volume for overflow mills; it may be anything desired with open-end mills. Shell liners are usually wave type.

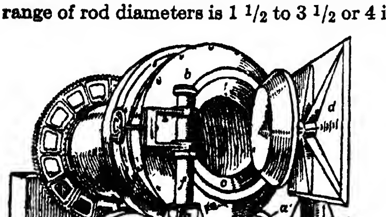

Fig. 26. Marcy open-end rod mill, discharge end.

Overflow-type mill (Fig. 25) is characterized by the fact that the shell *a* is supported, charged and discharged by means of the trunnions *b*. In the form shown, the trunnions are cast integral with the heads, which gives a strong and rigid structure. All parts that come in contact with pulp are lined (*d, e, f, g*). The mill shown, being designed for open-circuit operation, has a drum-type feeder. The discharge-trunnion liner is flared to prevent run-back of pulp to the tail-end bearing. Two manholes *q* are provided, spaced 180° to balance the weight of the covers; they are made large enough to permit entrance of shell-liner blocks *d*. End liners *e* are ordinarily made in one piece; when so made one or both heads must be removed for renewal.

Open-end mill (Fig. 26) has the discharge end carried on rollers *a*; the discharge head *b* has a large, centrally spaced lip-type opening *c*; a heavy door *d* mounted on a post *e*, independent of the shell proper, swings forward and is locked into place during operation by a hand-wheel-operated clamp mounted on post *f*, the closed position being such as to leave an open annulus for discharge of pulp, but to prevent splash and egress of rods.

p Estimated.
q C, 0.6–0.75%; Cr, 0.3–0.5; Mn, 0.5–0.7; Si, 0.15–0.25; S, 0.04 max.; P, 0.04 max.
r Weight 19,660 lb. Bolted and zinced in with 3,900 lb. Zn.
s 30 rods per week.
u Feed, <4-m.
v Best weight over the range of 12 to 19 tons.
w C, 0.96%; Si, 0.19; Mn, 0.81; S, 0.04; P, 0.03. Brinell, 295.
x C, 2.68%; Si, 1.22; Mn, 0.27; S, 0.177; P, 0.457. Brinell, 252.
y 100,000 to 110,000 tons.
z Maximum. Capacity of 2-stage circuit was increased about 10% by closing primary stage.

aa C, 0.87%; Si, 0.12; Mn, 0.62; Cr, 0.25; S, 0.05; P, 0.02%.
ab 1 1/2-in. plank backing.
ac C, 0.85%; Si, 0.14; Mn, 0.62; Cr, 0.25; S, 0.03; P, 0.03%.
ad Local. 5-in. excluding wave. End liners, single castings. About 15% scrap remelted.
ae Scrap loss, 8 or 10%.
af 0.46 for white cast iron.
ag Bolted and backed with 4,800 to 5,600 lb. Zn.
ah Shell, white iron; ends, Mn. Total weight, 38,650 lb.
ai Reject of about 4%, in 6- to 15-in. lengths, caught in discharge box.
aj White iron, 2 to 3 in. thick. Liner bolts, 1 1/2-in. 3/4-in. wood backing.
ak Mn lifter bars 3 5/8 in. high, spaced 11 in.; life 350 to 400 days.
al Rods pound, if less dense.
am Charged every 4 days; wired in bundles of 8; requires 20-min. stop.
an Maximum starting torque, 200% of full-load torque.
Cr-Mo Chrome-molybdenum steel.
CC Closed circuit.
OC Open circuit.

Peripheral discharge. A form of trunnion-mounted mill arranged for discharge around the shell periphery just in front of the discharge head has been advertised.

Construction. See Art. 4.
Rods. See Art. 6.

Manufacturers' data, as published, are summarized in Table 23. The catalogue ratings for tonnage to a given *mog* compared with 42 performance figures show 18 catalogue ratings higher than performances, 18 lower, 6 in accord, and an average excess of catalogue over performance for the 42 mills of only 4%. Feed size makes no difference as to direction of the discrepancies. The reduction ratios in the mills are definitely less than those implied in the catalogues. Catalogue ratings and mill performances are close together over the range of product sizes from 20- to 35-m.; the catalogues are, however, 10 to 20% on the conservative side in the coarser range, while for 48- and 65-m. the catalogue figures, especially for the larger mills, should be shaded 25 to 50%. Sufficient field data for comparison at yet finer meshes are not available, but the weight of practice is definitely against the use of rod mills in such service.

Capacities for very hard and tough ores will fall to about 50% of those for average ore, while those for soft easy-grinding ores may be double the average figures.

Dry rod-milling requires somewhat lower speeds (5 to 10%) and capacities are from 50 to 70% of those quoted (Table 23) for wet grinding, while making only about one-half of the reduction ratio, *i.e.*, reduction tons per hr. dry are from 25 to 35% of those obtainable wet. Reduction in power consumption is only slightly greater proportionately than the reduction in speed, which leaves the efficiency markedly lower. See also Sec. 6.

Performances at various plants are shown in Tables 24 and 25.
Size of feed. In modern practice feed is usually from 1/4 to 1-in. maximum.

Rose and Cramer (*IC 6358*) early reported from MOCTEZUMA that 1 3/4-in. feed was too coarse for 6-ft. primary mills at that plant, especially for the harder ores. Most manufacturers have not been willing, over the past several years, to recommend rod mills for feeds coarser than 1-in. The larger particles tend to resist crushing for a considerable time unless struck favorably, and until crushed will, of course, spread all pairs of rods between which they pass and thus remove effective crushing load from much of the finer material between such rods. It is possible that the newer large-diameter mills (*e.g.*, 9-ft.) and the smaller mills at high speeds may be able to handle somewhat coarser feeds if the ores are not too hard. The advantage of a larger diameter for treating coarser feeds is shown in Table 26. Both mills are at high speeds. Circuit comprises an open-circuit rod mill followed by a 5×10-ft. ball mill in closed circuit.

Material finer than 1/4-in. is not, normally, sent to rod mills except where granular products are desired, as for gravity or wet magnetic concentration, production of concrete sand (*9 #6 Civil Eng'g 341*), and the like. But see INTERNATIONAL NICKEL (Sec. 2, Fig. 144) and p. 51.

Table 26. Rod-mill grinding in Isabella section, Tennessee Copper Co. (*153 A 345*)

Rod mill: Diam. × length, ft.	5×10	6×9
Rods, diam., in.	3	3
Speed: R.p.m.	27.2	24.4
% of critical	73	71
Tons new feed per 24 hr.	725	825
Tons <200-m. produced per 24 hr. by circuit	314	417
Feed: Limiting size, in.	3/4	1 1/4
Product of two stages: Limiting mesh	35	48
% <200-m.	52.0	54.8
Power consumption of two stages:		
Hp-hr. per ton of new feed	6.9	8.2
Hp-hr. per ton of <200-m. produced	15.9	16.2
Steel consumption, lb. per ton:		
Rods	0.647	0.697
Balls	0.632	0.632
Manganese-steel liners, total	0.108	0.118
Cost, cents per ton:		
Grinding only	14.5	13.6
Crushing and grinding	22.4	18.5

Circulating load is normally smaller in primary rod mills than in primary ball mills. Tests at INTERNATIONAL NICKEL (*58 CMJ 665*) showed that while with ball mills capacity and efficiency both increased materially with increase in circulating load from 200 to 800% (see Art. 10), high loads were neither necessary nor desirable with rod mills.

Size of product in open-circuit rod milling depends on size of feed, character of rock, and feed rate. Characteristically the product from an average ore contains about 5% of tramp oversize (material on first $\sqrt{2}$-ratio screen finer than the limiting screen); the remainder, when plotted as in Fig. 27, shows a maximum concavity below a straight-line product curve of about 20%. Curves for hard ores and/or high feed rates fall in the shaded zone above the full-line average curve, while soft ores and/or low feed rates yield products with very small amounts of tramp oversize and relatively high proportions of fine sand, the curves falling in the shaded zone below the average curve. The heavy dotted line is an indication of what may be expected from the high-tonnage mills acting as secondary crushers, yielding high percentages of tramp oversize and relatively high percentages of fine sand, easily produced by rounding off, the percentages of coarser sands which must be produced by breakage being correspondingly small.

Characteristic curve for product of a circuit closed by a mechanical classifier is shown in Fig. 28. The coarse end of the curve is substantially the same as that for open-circuit grinding, but the fine end is slightly more concave. Essentially, however, closing the circuit with a classifier simply reduces limiting size to about half that of the mill discharge without changing the relative size distribution in the product.

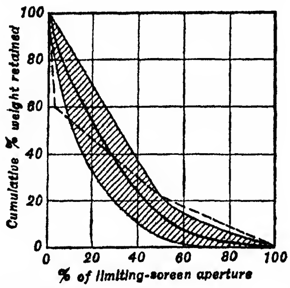

FIG. 27. Characteristic rod-mill product, open-circuit grinding.

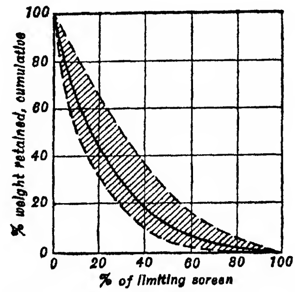

FIG. 28. Characteristic rod-mill product, closed-circuit grinding.

As of the 1930's, about half the rod mills in use were reducing to 20 or 28 *mog*, about 40% to 6 or 10 *mog*, and 10% to 35 or 48 *mog*. As of 1943 the trend is definitely toward increase in the percentage working to coarse *mogs*, while the use for *mogs* finer than 28 is exceptional.

Rod-mill product is remarkably similar in size distribution to roll product, as may be seen from Fig. 29 (*57 A 361*). This similarity is, of course, to be expected, in the light of Haultain and Dyer's work (Art. 2), since the rods in a slow-moving mill reasonably loaded act almost entirely like a large number of rolls with light spring pressures.

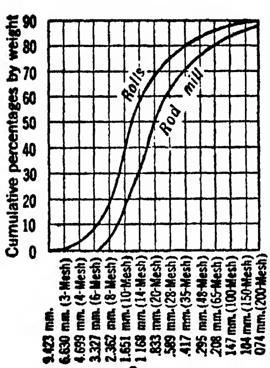

FIG. 29. Comparison of roll and rod-mill products (*after Watt*).

Coghill and Anderson (*117 J 1006*) warn that under certain circumstances the rod mill may, even while making a product that is not, as a whole, unduly slimed, nevertheless slime the mineral constituents excessively, and that the usual statement that the rod mill is a granulator and not a slimer is to be accepted with caution and discrimination. Table 27, giving the results of a thorough sizing-assay test on a rod mill crushing from 0.5- or 0.75-in. feed to 20 *mog*, is cited by the authors in support of this contention. Comparing the percentage of <200-m. in the product with that in products ground to the same limiting size in ball mills (Tables 30*a*, 32*a*, and 33*a*) it is apparent that the rod-mill product contains more slime and that the criticism is justified. But sliming has not been differential, as the authors imply; actually relatively more gangue than sulphide has been slimed in the case of silver, gangue and sulphide have been substantially equally slimed in the case of zinc, and only in the case of the lead has sulphide been slimed more than gangue; even here the differential is small. On the other hand, there has been impoverishment of the sizes from 20- to 200-m., which are the sizes in which table concentration is most effective.

Reduction ratios (limiting) vary, in the operations reported, from 2 to 47. Ratios above 30 represent old practice. Of the operations recorded in Table 24, 30% are working at ratios from 2 to 3 and 50% at ratios less than 8. No correlation appears to exist between efficiency, as measured in tons of production per hp-hr., and reduction ratio.

Capacity. For discussion of controlling factors see Art. 14. Analysis of the performance figures on 44 installations, given in Tables 24 and 25, is summarized in Fig. 30. Performance will fall to 25% of the graphed values for hard coarse feeds (>3/4-in.) to mills of small diameter, and may rise to 50% above the curves for fine feeds which grind easily. To estimate capacity for a given mill under given average conditions, multiply together the performance value from Fig. 30, the horsepower consumption estimated from Fig. 31, and the inch value of the *mog*. Adjust as above for unusual conditions.

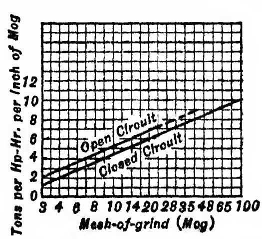

FIG. 30. Capacity of rod mills.

Table 27. Sizing-assay test of rod-mill grinding (*After Coghill and Anderson*)

Example. To estimate capacity, on an average ore, of a 5×10-ft. mill, charged to 40% of mill volume, grinding from $^3/_4$-in. to 8-m. open circuit. Read from Fig. 31, 2,600 lb. charge per ft. of nominal length and 6.85 hp. per ton of charge. Read from Fig. 30, 4.4 tons per hp-hr. per in. of *mog*. Read from Table 28, Sec. 19, 8-m. = 0.093 in. The tons per 24 hr. = (2,600 × 10 × 6.85 × 4.4 × 0.093 × 24)/2,000 = 875. For feed of larger size x multiply the above tonnage by the ratio $3/4x$. For harder or softer ores apply factors derived from Tables 44 to 49. For speeds different from the averages of Table 24, multiply by the ratio of the new speed to the average from the table for the corresponding diameter.

Capacity in tons per hr. per ton of rods averages 2.6 for 6 to 14 *mog*, 1.2 for 20 *mog*, 1.0 for 28 *mog*, and 0.5 for 35 and 48 *mog*, assuming feed <$^3/_4$-in. or smaller, and medium ore; add or subtract 50% for soft and for hard ores respectively.

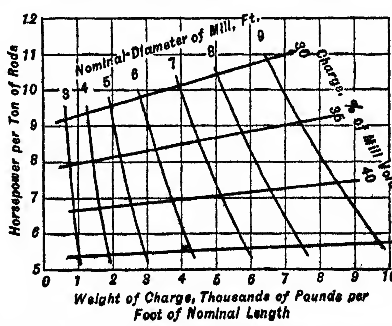

FIG. 31. Power consumption *vs.* charge volume in rod mill (averaged from Tables 24 and 25; speed included in averaging).

Power consumption varies primarily with weight of rods and diameter of mill as indicated by Fig. 31. It is to be noted that the response in power draft to a change in load is very much less for large mills than for small. Speed has, of course, a marked effect (*vide* the 6 $^1/_2$-ft. mills in Table 25), but the curves of Fig. 31 are reliable enough for estimate despite that speed was ignored in plotting the values from reported performances. Consumption is above average for rod loads far below normal, high ribbing on liners, high-moisture feed pulp, exceptionally hard ore, overspeeds, and relatively short mills. Mean consumption for mills of normal length-diameter ratio of approximately 2 : 1, and normal loading (charge volume about 40%) averages about 6.9 hp. per ton for mills up to 7-ft. diameter.

Operating relationships between power consumption, feed rate, and *mog* for mills of different diameters are shown in Fig. 32.

Efficiency. Figures for power consumed per ton of ore fed to the mill, disregarding feed size, size of mill, hardness of ore, and operating conditions, cluster around 0.40 to 0.45 tons per hp-hr. to 8 and 10 *mog*, 0.20 to 14 and 20 *mog*, 0.15 to 28 and 35 *mog*, 0.10 to 48 *mog*, and 0.07 to 65 *mog*. (See Fig. 32.) Material through 65-m. is produced in grinding to 28 *mog* and coarser at a somewhat higher average rate (0.10 tons per hp-hr.) than when the *mog* is 65. Reported performances are summarized in Fig. 33.

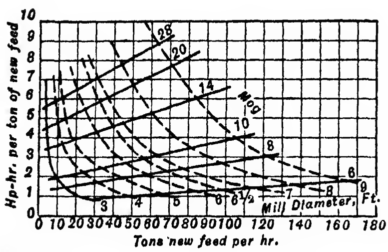

FIG. 32. Power consumption *vs.* feed rate and *mog* for rod mills.

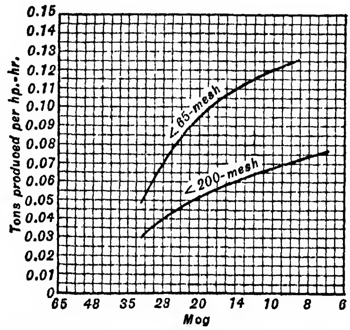

FIG. 33. Production of fine sizes in rod milling.

Speed for 26 mills reporting ranged from 38 to 68% of nominal critical speed. The low figures represent old practice or underloaded mills with speed cut down to save power input. Modern practice favors the higher operating speeds. The final limiting factor is the necessity to prevent throw of rods away from the shell and load at the top, since this tends to tangle the load. The range of satisfactory speeds for rod mills is shorter than that for ball mills.

Exhaustive tests at TENNESSEE COPPER Co. (*153 A 345*) showed that in single-stage closed-circuit grinding from 1-in. to 48 *mog* in a 6×12-ft. mill, increase in speed from 17 to 19 r.p.m. increased daily tonnage from 900 to 990, decreased power consumption from 13.9 to 13.3 hp-hr. per ton of feed, and gave a product containing 5.8% >65-m. and 58.3% <200-m. as against 6.0% >65-m. and 54.8% <200-m. at the lower speed. In open-circuit work, acting as a primary followed by two closed-circuit ball mills in parallel, the same mill was operated at 19 and 22 r.p.m. Operating data follow (19 r.p.m. first): Feed rate, tons per hr., 52.2, 51.8; hp-hr. per ton, 2.98, 2.70; size of feed, cumulative %:

	>1/2-in.	1/2~1/4	1/4~200-m.	<200-m.
R.p.m. 19	17.8	32.2	92.4	7.6
Do. 22	20.8	41.5	93.2	6.8

Products were substantially identical with 1% >20-m. and 25 to 26% <200-m. Consumption of manganese-steel shiplap liners was 0.088 and 0.069 lb. per ton, and of 3-in. high-carbon steel rods, 0.687 and 0.675 lb., respectively. Relative costs on the assumption of 15¢ per lb. for liner, 5¢ per lb. for rods, and 1¢ per kw-hr. for power are 6.97¢ and 6.43¢ per ton with a further credit of a fraction of a cent to the high-speed mill for the coarser feed taken.

The experience at TENNESSEE and at INTERNATIONAL NICKEL (p. 51) should answer the fears of operators for the mill liners at high speeds. C. F. Thompson of Mine & Smelter Supply Co. (*PC*) states that they recommend 73.5% of critical as maximum.

Pulp density ranges from about 75% solids for coarse feeds to 60% in fine-intermediate grinding. See also Art. 6.

Attendance. See Art. 18.

Lost time should be not more than 1%. The principal causes are charging rods and relining. Higher losses are usually due to improper bolting of liner, necessitating frequent tightening of bolts, and to tangling of rods. The latter is due either to too high speeds or, if worn rods bend instead of break, to the use of rods with too low carbon content.

Lubrication. See Art. 19.

Costs. The principal items are power and steel. Careful estimate should be based on local costs for these items and for labor applied to the performance figures given. For purposes of rough estimate, primary open-circuit grinding to 6- or 8-m. should cost from 5 1/2 (RAY, *134 A 327*) to 10¢ per ton, and 20-m. grinding 10 or 15¢ for average ores (1930's basis). Grinding to 48-m. will cost 20 to 30¢ per ton under best conditions unless the ore is definitely softer than average.

Use. Rod mills were originally adopted to obtain the economies of tumbling-mill grinding and yet make a granular product suitable for gravity concentration. They were highly successful in this field. With the switch to all-flotation in the mills in which they were used, it was, naturally, attempted to have them do the finer grinding thus made necessary. The trend of the last 15 years is superficially conflicting in that while in many plants the rod mills have been changed over to ball mills, at others they have been retained for fine grinding, and some new installations have been made for this service. This indicates, of course, that the matter is one of close decision. Conclusive experimentation is difficult and expensive, and results are hard to interpret. Individual predilections and the expense of the change-over, involving ordinarily a change in mill speed, and provision of larger classifiers and transport means for handling the larger circulating loads necessary, have played a large part in the decisions. Predominating opinion at present would seem to be, however, that when liberation demands grinding to 65-m. or finer the rod mill should not be used as a finishing mill, while for 35- or 48-m. finishing the rod mill can do satisfactory work and that a change involving any considerable expense would not be justified, particularly if the ore is not too hard and the feed to the grinding circuit is relatively coarse.

At International Nickel (*58 CMJ 665*) 6 1/2×12 1/2-ft. (I.D.) rod mills were installed in 1928 for one-stage grinding of 500 tons per 24 hr. from 4-m. to 48 *mog*. In 1938 the same mills were grinding 750 tons each through the same range. Conditions of operation follow:

Year	Rod load, tons	R.p.m.	Classifier	Circ. load, %	Hp. consumed
1928	25	16 1/2	Bowl	175	201
1938	22.5	18 1/2	FX	200	203

Screen tests, cumulative per cent. retained

Mesh	>4	8	14	28	35	65	100	150	200	<200
Feed	1.2	23.4	41.3	54.9	60.8					
Product 1928						6.2	15.6	29.4	43.1	56.9
Product 1938						6.1	15.4	32.6	52.9	47.1

The capacity of one mill was run up to 990 tons per 24 hr. by increasing speed to 24.2 r.p.m., rod load to 27 tons, and power draft to 305 hp. Screen analyses and hp. per ton of new feed were identical with the lower-tonnage performances.

Exhaustive tests comparing ball-milling on the same feed were run, one rod mill was converted to a grate mill with 33-in. discharge opening. With ball load to the mill axis and 16 1/2 r.p.m. power draft dropped to 150 hp. and capacity fell accordingly, *i.e.*, tons per hp-hr. were the same but capacity was off 25%. Increase in speed to 18 1/2 r.p.m. restored capacity partly; further increase to 23 1/2 r.p.m. was necessary to get back to a draft of 200 hp. Under these conditions the ball mill and parallel rod mill ground 750 t.p.d. each to the same grind, but circulating loads were 800 and 200%, respectively. (See Art. 11 for effect of circulating load on ball-mill capacity.)

It was found that while as high as 1,200% circulating load could be carried with the FX classifier in the ball-mill circuit, with corresponding increase in capacity, 400% was the maximum with the rod mill; above this figure the return sand practically stopped grinding action by the rods and the circuit ran away.

A test run was made at International Nickel closing the rod-mill circuit with a Hum-mer screen equipped with stainless-steel cloth. The product size was

Screen	>65	100	200	<200
Per cent. retained	1.3	11.0	43.2	56.8

Circulating load was reduced but selective overgrind of sulphide was lacking and metallurgy suffered correspondingly.

At Tennessee (*153 A 345*) the 1928 grinding plant comprised three 6×12-ft. rod mills operating with one mill as an open-circuit primary and the other two in parallel as closed-circuit secondaries. Feed was Symons disk product with 0.6% >1-in., 39.3% >1/4-in., and 7.2% <200-m. The grinding mills were charged with 3-in. rods and operated at 17 r.p.m., grinding 900 tons per 24 hr. to 6% >65-m. and 54.8% <200-m. at an expenditure of 14.0 hp-hr. per ton and consumption of 0.2 lb. of manganese-steel liner and 2.736 lb. of rods per ton of feed. In 1938, with a slightly coarser feed (3.5% >1-in., 41.5% >1/4-in.; 6.8% <200-m.) the three mills were arranged as one open-circuit primary rod mill running at 22 r.p.m. followed by two closed-circuit ball mills in parallel, also at 22 r.p.m. Feed rate was 1,250 t.p.d., product was 4% >65-m. and 59.7% <200-m. Power consumed was 11.4 hp-hr. per ton and steel consumption 0.113 lb. of liner, 0.695 lb. of rod, and 1.161 lb. of balls. The indicated saving is 6 to 7¢ per ton.

At Hollinger (*134 A 331*), with a moderately hard ore, old practice was to crush through 3/4-in. and then grind through 35-m. with a 7×15-ft. open-circuit rod mill followed by two 6×16-ft. closed-circuit pebble mills in series. After a 2-year testing program a new crushing and grinding plant was built comprising crushing to 3-m. and grinding to the same limiting size in the 7×15-ft. mills, converted to low-discharge grate-type ball mills, operating in closed circuit with large FX classifiers. Comparative results are given in Table 28.

At Ray (*134 J 327*) a 9×12-ft. mill (Table 24) in parallel with rolls operating in closed circuit with screens produced 3,000 tons per 24 hr. of ball-mill feed of substantially the same fineness as the roll product at a cost of 5.5¢ per ton *vs.* 8¢ per ton for roll crushing. The difference was largely in cheaper steel. In the ensuing change each 9×12-ft. rod mill replaced four 42-in. Garfield rolls. At Republic

(*143 # 2 J 90*) a 9×16-ft. mill, arranged for feeding both ends and discharging at the center through peripheral ports, grinds dry from 3/4-in. to 10-m., replacing three large crushing rolls. At CHINO (*IC 6394*) replacement of 42-in. rolls by 7×10-ft. rod mills decreased maintenance and power costs materially.

The modern consensus is that for the softer average and soft ores the rod mill is definitely superior from the standpoint of simplicity to a closed circuit comprising rolls or short-head cone, screens, and elevating means, for reducing from 3/4- or 1- or even, possibly, 1 1/2-in. limiting size to 6- or 10-m. It may also show a lower cost per ton of ore so reduced. This is particularly true with wet and sticky ores. It also simplifies dust collection in the crushing plant. For harder ores it is probable that rolls or cones are cheaper for the reduction range down to 1/4-in., particularly if multistage grinding with a rod mill in the primary position is to follow, since the rod mill can handle tramp oversize from such machines operating open circuit. On the other hand, there is danger with such a circuit that the rod-mill circuit, if closed, or the secondary circuit, with the primary open, will load up with coarse sand, if the crushing runs consistently coarse. For grinding to 48-m. or finer the preponderant weight of use is in favor of ball mills in the final position, whether the ore is hard or soft. For two-stage work on hard ores the consensus seems to favor ball mills in the primary position also.

McClelland (*Bul 342 CIMM 407*) argues against use of primary rod mills on the score that although they can be fed with 1-in. material, it is usually possible to get to a nominal 3/8-in. feed with 2-stage open-circuit crushing and that it is possible to do excellent work, as to both first cost and operation, ball-milling in one stage from 1 1/2-in. to 65 *mog* (citing the GUNNAR operation, Table 30). He also points out as a disadvantage of rod-milling in the crushing size zone that storage thereafter is impossible and that the difficulties of balancing in a multistage circuit therefore arise.

Ball mills are tumbling mills in which the grinding media are metal spheres, usually made of an iron alloy. Other shapes such as cones, cubes, octahedra, short cylinders, and irregular pieces of scrap metal have been tried, but today the spherical shape predominates almost completely. Shells are essentially cylindrical (Fig. 34, item *A*), cylindrical with conical heads (item *B*), or conical (item *C*). Rotation is about the axis of generation,

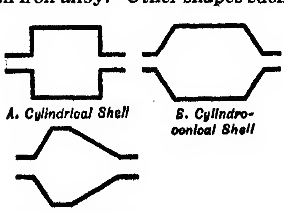

FIG. 34. Typical shell shapes for ball mills.

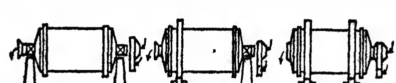

FIG. 35. Methods of support of ball mills.

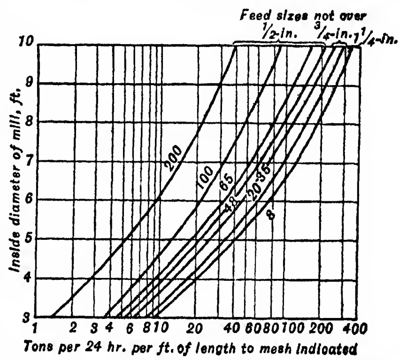
which is set horizontally. The shell may be fitted with a transverse perforated diaphragm near the discharge end, in which case, it is designated a GRATE MILL (Art. 10); otherwise it is an OVERFLOW MILL (Fig. 34). Support may be by means of trunnion bearings at both

ends; by trunnion at the feed end and tire and rollers at the discharge end; or by tire and rollers at both ends (Fig. 35). Two-trunnion support is usual for overflow mills and is often used for grate mills. Tire-and-roller support permits elimination of the discharge head in grate mills, thus allowing discharging pulp to flow from the periphery of the shell unimpeded, affording superior facilities for observation, and more ready access to the shell interior. Such mills are called OPEN-END MILLS. A mill with trunnion discharge is called a HIGH-DISCHARGE MILL in contradistinction to LOW-DISCHARGE MILLS, which have grates with openings extending nearly all or all the way to the shell liners. Cylindrical mills with trunnion feed and peripheral discharge through a screen are called SCREEN-TYPE or Krupp ball mills; they are substantially obsolete in wet milling.

8. OVERFLOW BALL MILLS

Overflow mill is essentially like the two-trunnion rod mill (Fig. 25) except that, in general, the ratio of length to diameter does not exceed $1\ ^1/_2 : 1$. Principal structural elements are discussed in Art. 4. Usual sizes and operating data presented by the manufacturers are summarized in Table 29 and Fig. 36. Diameters in ordinary use are 5 to 10-ft.

Table 29 contains data both as to overflow- and grate-type cylindrical mills. The lighter mills and smaller ball loads at any rated size usually refer to overflow mills. VOLUME OF LOAD was calculated in the table on the basis of 300 lb. per cu. ft. of struck volume, as indicated by Gow (*134 J 203*). Most manufacturers calculate on the basis of lower weights per cu. ft. whence the intended mill volumes are greater than the tabular values. Usual practice is to carry loads as large as the mill will hold, which is between 40 and 45% of mill volume for mills with normal-sized trunnions, decreasing the load somewhat if less than full capacity is desired. The SPEEDS recommended comprise the usual range (see Table 30), except that speeds above 80% of critical are unusual and probably mark a difference between manufacturer and author as to the liner thickness assumed.



For grate-type mills, add 10%; for overflow mills, deduct 10%; for very hard, tough rock, deduct 50%; for soft rock add 25 to 50%.

FIG. 36. Average capacities of ball mills on average ores; wet closed-circuit operation (*after seven manufacturers*).

Performances of overflow ball mills are given in Table 30.

Size of feed at 24 mills reporting ranged from <2-in. to 28-m. with half feeding at 3-m. and smaller.

Size of product ranged from 3 to 65 *mog* with the mean at 28 to 35 *mog*. The predominant discharge size in primary grinding was 10 *mog* and in secondary 48 *mog*, reflecting the fact that the majority of mills reported were grinding in either one or two stages for flotation feed.

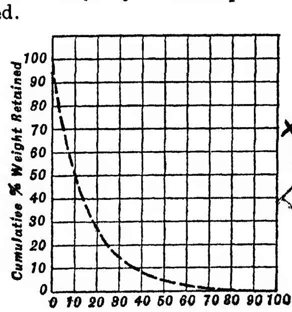


FIG. 37. Characteristic product of overflow ball mill, open-circuit grinding to 8 or 10 *mog*.

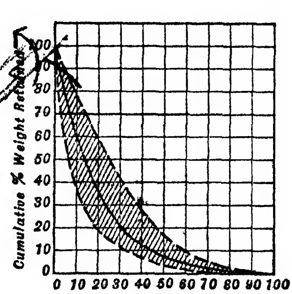

FIG. 38. Characteristic product of overflow ball mill (closed-circuit grinding).

Distribution curves are shown in Figs. 37 and 38. The solid curve in Fig. 38 is the mean. In closed-circuit work, if sizing stops at 200-m., short-range products for average

ad Length is that of cylindrical barrel; 60° conical ends.
ae Shiplap surface conformat.
af Average thickness 3 in.; 20 waves per circle; weight, 25 tons.
ag *IC 6343*.
ah Williamson mill.

ores will lie between the full curve and the upper dotted curve, and long-range products below the full curve. For the same size range, the curves for hard ores lie above the full line and those for soft ores below. The 80% size ranges from 20 to 45% of limiting size. Fifty per cent. of the product from an average ore is less than 15% of limiting size, in general, and less than 10% on a soft long-range product. Fig. 37 shows an average 8- or 10-m. open-circuit product, based on three ores slightly on the soft side of average hardness.

Reduction ratios. Nominal limiting ratios range from 1.4 to 240 with the mean about 4. The 80% ratio ranges from 1.4 to 164 with the mean about 6. These mean ratios correspond to prevailing practice of reduction of 3/8- or 1/2-in. to 8 or 10 *mog* in the primary of two-stage grinding, and 10-m. to 48 or 65 *mog* in secondary work. The high ratios denote, of course, the one-step reduction of >1-in. material to flotation feed; the frequency of this practice in the cases reported is about 8%.

Capacity. For discussion of controlling factors see Art. 14. Averages of the performances in Table 30 are graphed in Fig. 39, with ranges indicated by verticals, and the numbers of cases indicated by the numerals adjacent the range lines. Low values represent hard ores or mills operating at low speeds and/or with small ball loads. The dotted line probably represents safe figures for estimate on average ores at about 40% ball load, with higher figures definitely to be expected when grinding softer ores. For estimate, apply the method

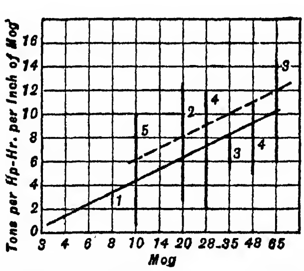

FIG. 39. Capacity of overflow ball mills.

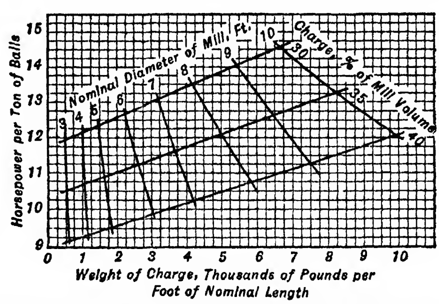

FIG. 40. Power consumption *vs.* charge volume in overflow ball mills (averaged from Tables 29 and 30; speed 70 to 75% of critical).

of p. 49 to Figs. 39 and 40. Capacity in tons per hr. per ton of balls averages about 3 for 8 to 10 *mog* and 1 for 28 to 65 *mog*, from which an average of 2 for 14 to 20 *mog* is inferable. These figures should not, theoretically, have any diagnostic value, since they should vary both with diameter of mill and size of feed as well as with speed, charge volume, and grindability. But as a matter of practical fact they are useful for average ores and mills over 5 ft. inside diameter working to reduction ratios near the mean and to *mogs* down to 65. Low reduction ratios and 9- and 10-ft. diameters tend to give capacities above the averages.

Power consumption at usual speeds and ball charges with partially worn wave-type liners may be estimated from Fig. 40, which is averaged from the performance figures in Table 30, and from the estimates of Table 29. With relatively smooth liners and speeds below 70% critical, consumption figures will be lower, although the increase in mill diameter and charge weight as a ridged liner wears smooth tends to keep power up or may even cause it to rise. The effects of feed rate and *mog* on power consumption are indicated in

Fig. 41, averaged from Table 30. The data apply to 7-ft. mills only, there being an insufficient number of cases for other sizes.

Efficiency. Tons per hp-hr., disregarding all other variables, cluster around 0.3 for 8 or 10 *mog*, about 0.25 for 14 to 28 *mog*, and 0.1 for 35 to 65 *mog*. Markedly higher figures correspond to soft ores and low reduction ratios (*e.g.*, LEADWOOD and ARTHUR, Table 30), and exceptionally low figures to high reduction ratios and/or hard ores (GUNNAR, BUTTE & SUPERIOR 8×6-ft. mill). Production of <65- and <200-m. material when grinding to different *mogs* is averaged in Fig. 42. It is doubtful whether the trough at 28 *mog* is significant; rather it would appear that the dotted lines presented a more reasonable expectation.

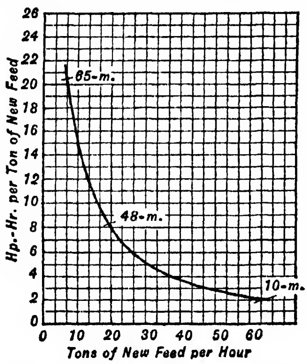

FIG. 41. Power consumption *vs.* feed rate and *mog* for 7-ft. overflow ball mills.

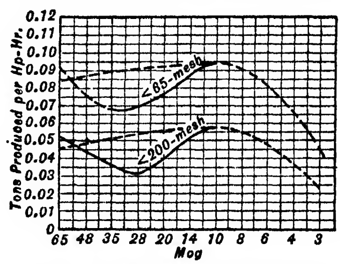

FIG. 42. Production of fine sizes in overflow ball mills.

Speed ranged from 53 to 86% of critical with mean and average both in the range of 70 to 75%. The higher speeds in general correspond to hard ores or coarse feed and *vice versa*. See also ***Speed*** in Art. 7.

Pulp density ranges from about 50 to 85% solids. Values below 65% solids are exceptional. Usual practice is around 70% solids for the finer feeds grinding to 48 or 65 *mog* and about 80% for coarse feeds and 8 or 10 mog. See Art. 16.

Attendance. See Art. 18.

Lost time should not exceed 1%. The principal cause is relining.

Costs. See Art. 20.

Use. For discussion of overflow *vs.* grate-type mills, see Art. 3.

9. CONICAL BALL MILL

The true conical mill is characterized by a shell having a short cylindrical section and a relatively acutely conical discharge-end section (see Fig. 34, item *c*, and Fig. 43). The usual form (HARDINGE) is also provided with an obtusely conical feed end. The generating elements of the conical end sections make approximately 60° and 30° angles with the mill axis. The ratio of diameter to length of cylindrical section in the typical mills is from 3 to 4.5 : 1 (see Table 31), but many so-called conical mills are built with ratios as low as 1.7 : 1, and the manufacturer lists conical-ended mills with a D/L ratio as low as 1.2.

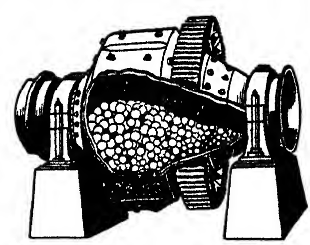

FIG. 43. Conical ball mill.

Action in a conical mill with a high D/L ratio is different from that in a cylindrical mill for two reasons. First, the critical speeds for a given r.p.m. increase as the diameter of the transverse section decreases, wherefore the percentage of critical speed and the consequent lifting effect on the load is markedly greater in the cylindrical section than along the discharge cone. This tends to heap the load in the cylindrical section. Second, at the toe in the conical section the mill shell imparts a longitudinal impulse toward the cylindrical section. This impulse is most effective on the surface material, which is to say the larger balls and any coarse particles of ore. Hence the larger balls tend to segregate to a certain extent in the cylindrical section (Art. 3), and coarse material tends to be held or returned there until it is broken. The piled-up charge exerts a greater superincumbent load than that attainable with a ball charge having the same struck-volume level in a cylindrical mill of the same diameter. These tendencies are all increased when the mill is run at cataracting speeds.

Table 31. Conical ball mills. Manufacturer's data

Size, b diam., ft., × length, in.	Weights, lb.		Ball charge		Speed, r.p.m. d	Power, hp.			Estimated capacities, tons per hr. a

a On average ore.
b Standard sizes.
c Corresponding to 35 to 50% of mill volume on the basis of new liners and 300 lb. per cu. ft. struck volume of ball charge.
d Corresponding to 65 to 85% of critical on the basis of inside diameter of new liners in cylindrical section.

The finer pulp, on the other hand, forming with the water a relatively viscous pseudo-fluid, is lifted with the heaped-up ball charge in the cylindrical section into a position of accentuated elevation above the lip of the discharge trunnion. This results in a more rapid flow toward the trunnion and thus accelerates discharge of this material. It is not improbable, further, that with pulps of sufficient viscosity to cause relatively sluggish flow through the ball interstices, there is no continuous body of interstitial pulp through the cylindrical section, but rather that most of the pulp therein is in the form of coatings on the balls. This has the effect of making this portion of the mill act as a low-level cylindrical mill.

Discharge restrictions are necessary when conical mills are operated with high ball charges. Fig. 44 shows a discharge-trunnion liner *a* which can be bolted on in place of the usual discharge bell (*b*, Fig. 45). This high-level spout had the double effect of raising the pulp level in the mill and hindering ball discharge.

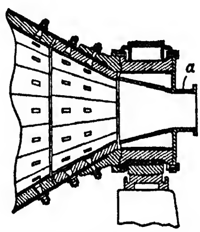

FIG. 44. High-level discharge spout.

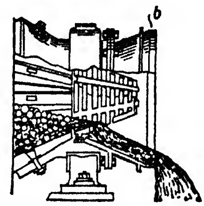

FIG. 45. Cone grate.

Grates. The cone grate (Fig. 45) is simply a conical grizzly bolted to the inner end of the discharge bell and trunnion liner *b*. Its function is to hold back balls in a high ball charge and yet permit a relatively low pulp overflow. Reverse-cone grate (Fig. 46) is essentially the reverse-cone liner perforated except that it is smaller, lighter, and is carried on a high-level spout. Fig. 47 shows a form of grate for use when it is desired to convert a conical mill to a straight low-discharge mill. The effect is to approximate a short cylindrical grate mill, in so far as action within the mill is concerned.

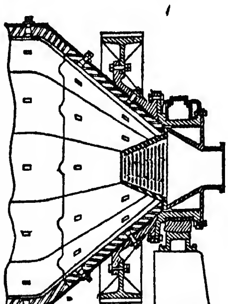

FIG. 46. Reverse cone grate.

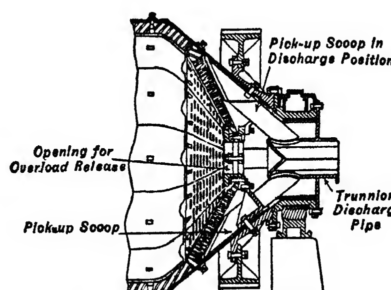

FIG. 47. Low-level grate.

Manufacturer's data are given in Table 31. The speeds recommended cover a range of 65 to 85% of critical in the cylindrical section based on new liners of average thickness. The ball loads recommended comprise the range from 35 to 50% of mill volume, likewise based on new liners.

Performances of conical ball mills are given in Table 32.

Size of feed to primary mills at 48 plants reported ranged from 8-m. to 1 $^3/_4$-in. limiting. At 26 of the plants the limiting size was in the range of $^3/_8$- to $^3/_4$-in. and at 14 of them in the range of 1- to 1 $^1/_2$-in. At only 6% of the plants was the feed smaller than $^1/_4$-in. limiting size.

Size of product from primary mills in multistage grinding ranged from $^3/_8$-in. to 35-m. limiting; at 13 out of 32 mills in such service the grind was to 8 or 10 *mog*, and at 9 to 14 or 20 *mog*. Ten out of 20 mills in one-stage service finished at 48 *mog*. Of 6 mills reported in secondary and tertiary service, two finished to each of the sizes 48, 65, and 100 *mog*. In so far as the reports constitute a representative cross-section of conical mills in ore-milling practice, their field is in one-stage or multistage grinding for flotation, or as a primary, followed by tube mills, in multistage grinding for cyanidation.

a Outside dimensions.
b Based on new liners of average thickness.
c See Table 47, Sec. 22.
d Numbers refer to columns in Table 32*a*.
e Estimated.
h Sec. 4, Art. 2.
i Art. 12.
j *IC 6314*. Primary mill taking high-grade gravity middling.
k *IC 6314*. Two secondary mills in parallel dividing classifier sand from product of primary mill, note *j*.
l Relatively hard.
m Hardinge Co., *PC*.
n Circuit closed with a screen.
o Relatively soft.
p Britannia type, Art. 5.
q Extremely hard.
r Extremely soft.
s Steel punchings, 1 to 1 1/4-in. diam. × 1/2-in.
t *IC 6261*.
u C, 1.06%; Mn, 0.687; Cr, 0.338; Si, 0.076; *P*, 0.02; *S*, 0.034%.
v 1 in. thick.
w At 16 1/2 r.p.m. and 9 tons of ball charge the tonnage ground to 48 *mog* was 60% less with only 20% less power.
x McGill, Nevada, plant.
y *140 #4 J 38*.
z Total weight, *19,382* lb.
aa Life: In feed cone, 140 to 160 da.; in cylinder, 365 da.; in discharge cone, 260 to 300 da.
ab *IC 6550*.
ac Composition: C, 0.92%; Cr, 0.15; Mn, 0.62; Si, 0.24; P, 0.03; S, 0.05%.
ad Life of different sections, in days, averages as follows:

Section	Feed cone		Cylinder	Discharge cone		
	Entrance half	Basal half		Basal third	Center third	Discharge end
Liner plate	170	242	204	192	408	640
Wedge bar	....	158	170	178	289	....

Liner is inspected every 2 weeks and thin sections are replaced. Sand penetrates under liner and wears shell, to a maximum extent near the inlet; this part of the shell required replacement after 5 years.
ae At 1,100 tons per 24 hr. <200-m. was 21.4% and the product of the secondary circuit (next column) was 3.5% >48-m. and 47.9 <200-m. Compare screen test *20*, Table *32a*.
af *IC 6314*.
ag One at 20 and one at 21 r.p.m. The higher hourly tonnages and power consumption correspond to the faster mill. Feed and products are reported combined.
ah *IC 6430*.
ai Feed-cone liners, 8 mo.; cylinder, 14 to 16 mo.
aj *IC 7073*. Three primary mills.
ak For wears at different parts of mill see Art. 5.
al Unknown. A rough estimate may be made from the flowsheet, Sec. 2, Fig. 118, and from the screen tests, Table 32*a*.
am 3 secondary mills.
an Tertiary mill.
ao 200 tons total feed per hr. per mill.
ap Reverse-cone grate with high-level discharge.
aq At 25-ton ball load new feed is 22.5 t.p.h. and hp. consumed 261; at 24-ton load the corresponding figures are 21.6 and 252.
ar Scrap loss, 32%, included.
as Unit cell in circuit.
at Primary mill
au Tonnage is feed to a desliming classifier that precedes. Mill discharge to rake classifier, overflow to bowl, both sands return to mill.
ay Based on new liners of average thickness and 300 lb. per cu. ft. of struck volume for ball charge.
az Scrap is 58% of total.
ba Scrap is 64% of total.
bb Scrap is 60% of total.
bc Scrap is 61% of total.
bd Scrap is 29% of total.
be Mill discharge to the amount of about 200% of new feed recirculated directly from mill discharge in order to aid in introduction of coarse new feed.
bf Cr-Mo grate 1/2 to 3/4-in. slots (see Fig. 47).
bg Nominal. See Table 32*a*, note *k*.
bh Tons <100-m. per hp-hr.

a All <1 1/4-in.
b Through last screen.
c Estimated from screen tests and tonnages of primary and secondary circuits.
d New feed same as (10).
e New feed same as (13).
f New feed unknown, since it forms a part of classifier sands.
g Total feed to mill; new feed unknown.
h 81% <325-m.
i New feed same as (40).
j New feed same as (42).
k 9.5% >1 1/2-in.; some as coarse as 4-in.
l *CF*, composite feed; *CO*, classifier overflow; *CS*, classifier sands; *MP*, mill discharge; *NF*, new feed.
m 31.5% <325-m.
n 21% <325-m.
o 10.3% <325-m.
p 48.3% <325-m.
q 4% >1 1/2-in.

Distribution curves are shown in Figs. 48 and 49. The solid curves are the means. The points cluster rather closely to the mean except in the case of short-range lightly ground secondary and tertiary products fed with classified sands, with circuits closed by rake-type classifiers. Curves for such products tend to fall as much as 10 or 15% above the mean in the size range from 15 to 50% of limiting. Upward of 55% of open-circuit products and somewhat more than 50% of closed-circuit products are finer than 10% of limiting aperture.

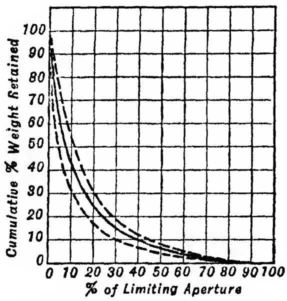

FIG. 48. Characteristic product of conical ball mill (open-circuit grinding).

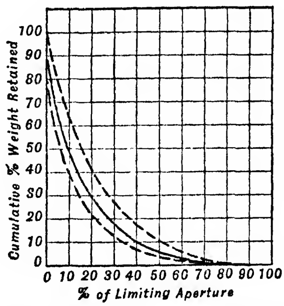

FIG. 49. Characteristic product of conical ball mill (closed-circuit grinding).

Reduction ratios. Nominal limiting ratios range from 2 to 344 with the mean about 15. The range for the 80% ratio is 2.4 to 130 with the mean about 12. In 18% of the mills the limiting ratio is less than 5, and in 65%, less than 30. The low ratios correspond, of course, to high-tonnage primary service, either open circuit or with small circulating loads, and to secondary and tertiary grinds. The very high ratios go with low-capacity one-stage practice with relatively coarse feeds. The mean corresponds, in general, to one-stage flotation grinds from feeds about $^3/_8$-in. size, and to relatively fine primary grinds of coarse feeds in both flotation and cyanide mills.

Capacity. The averages of the performance tables are graphed in Fig. 50. The ranges in values are indicated by the verticals, and the numbers of cases by the numerals set beside

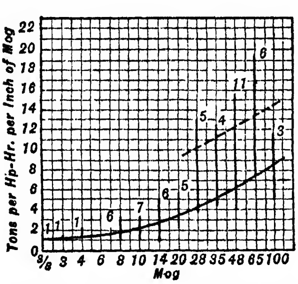

FIG. 50. Capacity of conical ball mill grinding ores wet.

the verticals. For use of the curve in estimating capacities see Art. 7. For discussion of factors affecting capacity see Art. 14. The long upward extensions of the verticals in the range from 28 to 65 *mog* correspond to small reduction ratios in secondary grinding, and the values for such service are better indicated by the dotted curve. Sporadic high values of 119 tons at 100 *mog*, corresponding to a tertiary grind with a reduction ratio of 3, and 25 tons at 200 *mog*, corresponding to the grinding of a very soft barite, are not plotted.

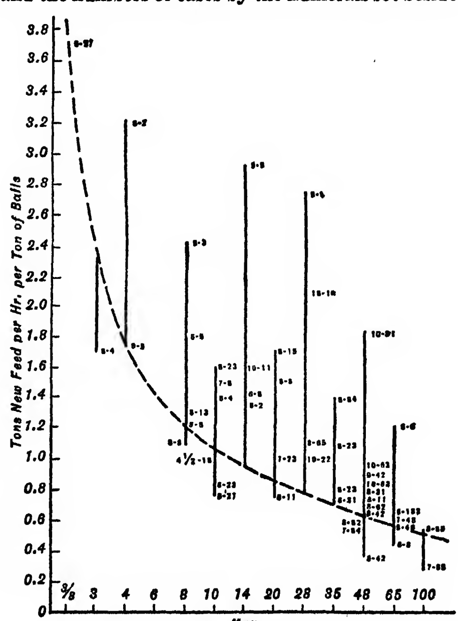

FIG. 51. Capacity of conical ball mills in terms of ball charge when grinding ores wet.

The relationship—or lack of consistency therein—between capacity and ball charge is shown in Fig. 51, in which the verticals represent the spread in values at the different *mogs*, and the numbers are, respectively, the mill diameters and the reduction ratios. There is, of course, a rough inverse relationship between capacity and *mog*, as indicated by the curve. There is also a further rough relationship of capacity to reduction ratio, as indicated by the general trend of the low values for reduction ratio to cluster around the upper ends of the verticals. Finally the large mills can, in general, do more work with a ton of balls than the small mills, which is to be expected from the fact that the horsepower per ton of balls increases as mill diameter increases. In some cases operations occupying unduly low positions on a given vertical are attributable to very hard ores, *e.g.*, the low position of point 8–11 at 20 *mog* (WRIGHT-HARGREAVES) and the relative positions of the two 6-ft. mills at 65 *mog*.

Charge volume can be held higher in a conical mill without a ball-retaining grate than is possible in cylindrical mills because of the tendency of the ball charge to heap up in the cylindrical section. This explains the relatively high volumes found in several nongrated mills.

Power consumption per ton of balls in the usual speed range (75 to 80% of critical) averages 9 hp. per ton for 6-ft. mills, 10 hp. for 8-ft. mills, and 11 hp. for 10-ft. mills and varies roughly with the percentage of critical speed either side of this range. Variation with feed rate and *mog* are shown in Fig. 52, averaged from Table 32, but the values from this figure must be used with due consideration for character of ore and operating conditions, and extrapolation at either end is not justified.

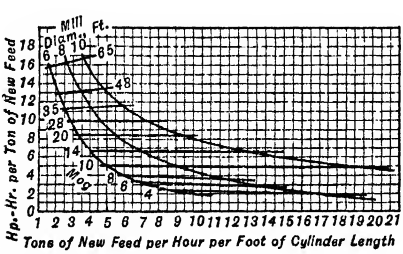

FIG. 52. Approximate relationship between capacity and power consumption for conical ball mills (after Table 32).

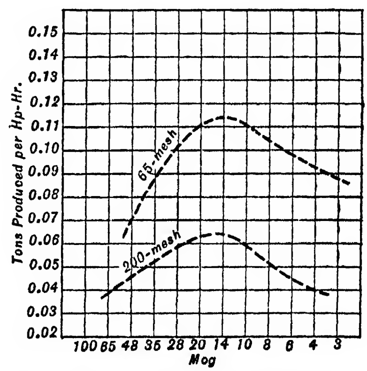

FIG. 53. Trend in production of finished sizes in 8-ft. conical ball mills.

Efficiency. Tons of new feed per hp-hr. is affected by feed rate, *mog*, and size of mill, as shown by Fig. 51, as well as by the character of the ore, as is mentioned in the discussion of that figure. Tons <65-m. and <200-m. produced per hp-hr. are additionally influenced by the size of feed, and probably the effect of the *mog* is accentuated. Fig. 53, which represents very rough trends only, as shown by the 8-ft. mills of the table, indicates maximum production of these fine sizes per unit of power when the *mog* is 14. To the extent that the data are representative, they indicate that primary grinds aimed at this *mog* should produce the maximum quantities of these finished sizes per unit of power.

Speed ranged from 61 to 100% of critical with both mean and average in the range from 75 to 80%. The only apparent correlation from the table is a tendency to run the larger mills somewhat slower than the small ones. The smaller mills represent older practice.

The 10×72-in. mill GOLD ORE, Table 32, was run (*PC*) at 21.8 r.p.m. with all other operating conditions the same except that feed rate averaged 30 t.p.h. Power consumption was 492 hp. Product contained 10.8% >65-m. and 53.7% <200-m. *i.e.*, was slightly coarser than at the lower speed despite the lower tonnage. Tons new feed per hp-hr. was 0.061, off 10%; tons <65-m. produced per hp-hr. was 0.047, off 15%; tons <200-m. produced per hp-hr. was 0.028, off 26%.

Pulp density ranges from 34 to 83% solids. In general the thinner pulps represent the older practices. Recent practice tends toward slightly more water in the finer pulps, but the differences are not great See also Art. 16.

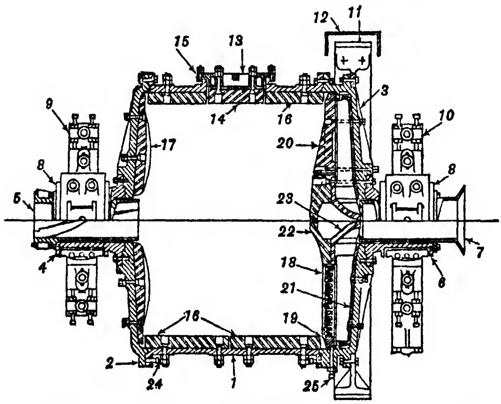
Attendance. See Art. 18.

Lost time. The principal cause is relining. The total should be less than 1%.

Costs. See Art. 20.

10. CYLINDRICAL GRATE BALL MILLS

Grate ball mill is a cylindrical mill with the same general dimensions as the overflow ball mill (Art. 8), but furnished with a grate near the discharge end of the shell. It may be of open-end type, in which case discharging pulp flows directly from the shell periphery or over a low annular weir, and the discharge end, at least, is ring-and-roller supported.



Legend, Fig. 54.

1. Shell. Usually cast; may be rolled plate.
2, 3. Detachable heads.
4, 6. Detachable trunnions.
5, 7. Trunnion liners; stud-bolted to outer faces of trunnions.
8. Trunnion bearings.
9, 10. Sole plates.
11. Driving gear.
12. Gear guard.
13. Manhole cover.
14, 16, 17, 21. Shell and end liners.
15. Manhole gasket.
18. Grate.
19, 20. End and side clamp bars, respectively, for grate sections.
22. Center-discharge liner.
23. Discharge cone.
24. Jack screw.
25. Grate-adjustment screw.

FIG. 54. Marcy grate ball mill, 2-trunnion type. Horizontal section with half-plan on bearings and sole plates.

More commonly the mill is of the two-trunnion type, Fig. 54, and some sort of pulp elevator is provided between the grate and the discharge-end head to lift pulp that passes through the grate into the discharge trunnion.

Grates. The simplest form of grate is a one-piece cast grid attached to the end of the shell of an open-end mill. A modification thereof designed and used at HOLLINGER (*HS*) in converting open-end rod mills to open-end grate-type ball mills is shown in Fig. 55. It consists of a cast-steel frame *A*, 2 in. thick by 8 ft. O.D., bolted to the flanged end of shell *S;* sectional cast grates *G*, 2 1/2 in. thick, with tangential slots tapering outwardly from 3/8-in. aperture to 3/4-in., provided with 3 handles *H* of 1/2-in. forged-steel rod cast in place, and held in place by wedge-shaped bars (not shown) which bolt to the inside of and protect the spokes of the frame; an imperforate cover *C* for the central manhole *M*, with liner *L;* and ring liners *R*, all liners being made of white iron and bolted to the corresponding part with 1-in. forged-head bolts. Discharge ring *D* is made of 5/8-in. plate, bent, welded at the bend, and bolted to the outside of the grate. It was found that the cast-steel grates chipped and peened in service; they were then burned back to proper aperture and hard-surfaced, whereupon the difficulty ceased. COST was about as much as that of a new cast-steel grate; white-iron grates discarded when worn (@ 60 da.) are probably cheaper. Some manufacturers make grates of similar construction with alloy-steel grates and spoke bars, with 10 instead of 8 spokes, and with the slots arranged radially, or with the slots of the inner half of the grid section tangential and the outer half radial. In other forms rectangular or rounded holes replace the slots.

Grates for trunnion-discharge mills are spaced a few inches inside the discharge-end head (Fig. 54) and are provided with radial or spiral fins or lifters (Fig. 56) terminating near the center on a conical projection (item 23, Fig. 54), which directs the lifted pulp into the discharge trunnion. The latter may be fitted with a liner having a rim at the inner end to lessen spill back into the shell.

In the form shown in Fig. 56, a cylindrical liner box *a* carrying the lifters *b* (spiral or radial) is bolted to the inside of the discharge head *c* and carries the grid on its inner end.

A more elaborate form with provision for adjusting the height of discharge through the grid is shown in Fig. 57. The diaphragm frame *a* comprises a transverse casting *a* with coned center *n* from which radiate ribs *k* extending to the mill head *p*. The diaphragm is bolted to the head by bolts *f*. It is perforated by several circumferential rows of relatively large round holes *l*. Rectangular grates *b* are made up of tempered high-carbon tool-steel bars milled to a transverse taper, leaving suitable spacer sections, drilled and riveted together. The grates are held to the inner face of the diaphragm, suitably spaced therefrom, by wedge blocks *c*, which, in turn, are bolted into place by through bolts *d*. Liner blocks *g* held by bolts *e* protect the remaining inner surface of the diaphragm. A central discharge pipe *h*, projecting through the center of the trunnion, acts as an emergency overflow. If no such provision is made, an overloaded mill will discharge back through the feed trunnion and may require several hours to work back to normal. Pulp gradient in the mill is controlled by plugs inserted into the holes *l*, to which access is had by handholes *m*, suitably spaced.

Grate apertures range from 1/4 to 1 in. according to the size at which it is desired to reject balls. The greater the spacing the less interference with pulp flow and the less the likelihood of blinding by wedged balls, wood, hemp, etc. Total area of opening should be as large as possible when high tonnages of pulp are to be put through the mill. The interior surface should be reasonably smooth. Taper should be definite and continuous; 1/8 in. each side of a bar is usually considered sufficient. Increase in tendency to blind with increase in thickness usually limits life to twice liner life. The grate has no function in control of size of mill product except as it controls pulp gradient.

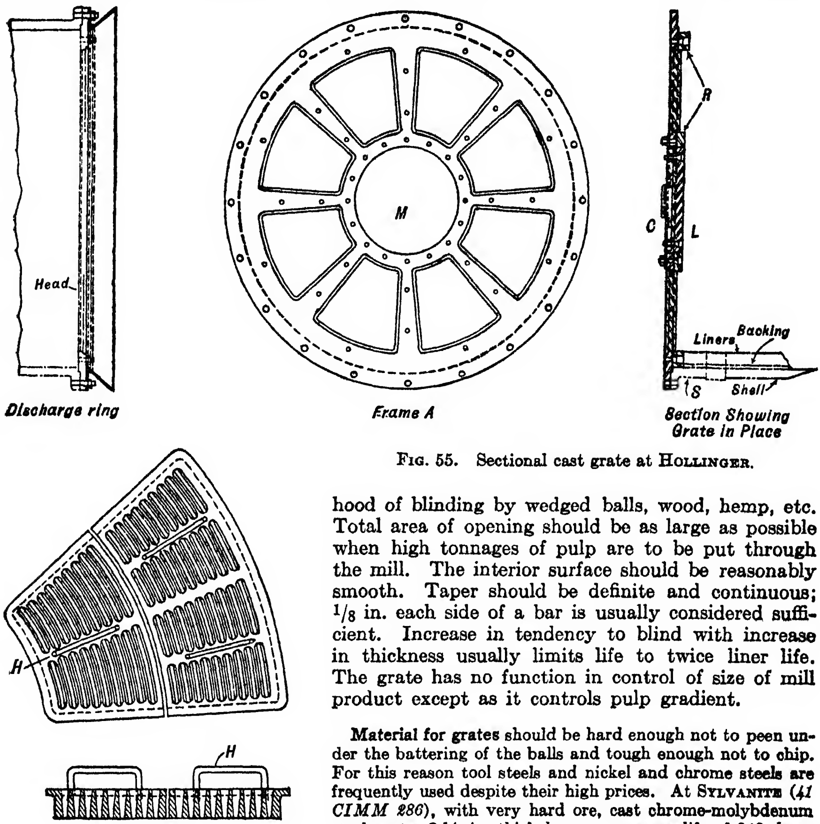


Fig. 55. Sectional cast grate at Hollinger.

Material for grates should be hard enough not to peen under the battering of the balls and tough enough not to chip. For this reason tool steels and nickel and chrome steels are frequently used despite their high prices. At Sylvanite (*41 CIMM 286*), with very hard ore, cast chrome-molybdenum steel grates 3 1/2 in. thick have an average life of 240 days.

Manufacturers' data. See Table 29.

Performances of grate ball mills are given in Table 33.

Size of feed to the 58 mills reported ranged from 2-in. to 48-in. but at 12 mills out of the 58 the feed was in the size range of 1- to 2-in. limiting size, and at 10 in. the range 1/2- to 1/4-in. Only 23% of the mills report feeding at sizes finer than 1/4-in. limiting.

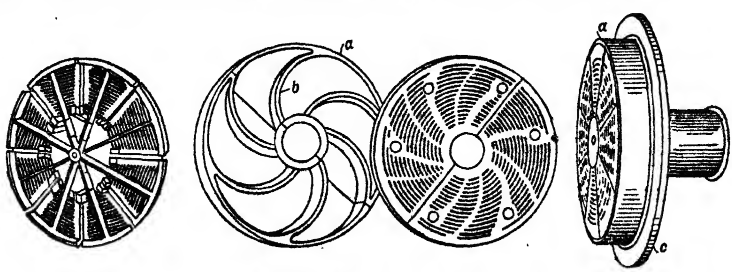

Fig. 56. Mill-head elevators with grates.

Size of product from the 58 mills reported ranged from 3 *mog* to 150 *mog*. Twenty-one of the mills were in primary service in 2-stage grinding, and of these 8 discharged at 3 to

20 *mog* and 10 at 28 to 35 *mog*. Eight of the total were doing one-stage grinding for flotation. Only 2 were in secondary service (but see grated tube mills, Art. 11). Based on this particular random cross-section of practice, the field of the grate ball mill is definitely in primary or one-stage service delivering in the range of 28 to 65 *mog*.

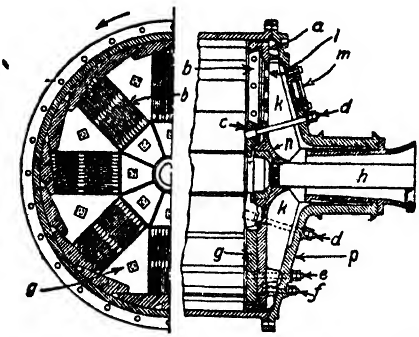

FIG. 57. Grate discharge for Allis-Chalmers ball mill.

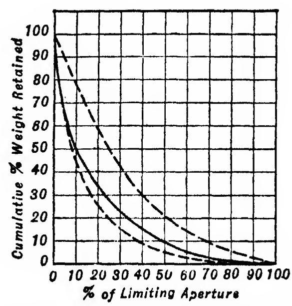

FIG. 58. Characteristic product of grate ball mill (closed-circuit grinding).

Distribution curves are shown in Fig. 58. The solid curve is the mean. Sizings of fine short-range products and tough feeds lie between the mean and the upper dotted curve; those for relatively coarse products lie below the full curve. The 80% size is 20 to 50% of limiting size. Fifty per cent. of the product of a 48- or 65-m. grind of an average ore is finer than 10% of the limiting aperture of the product.

Reduction ratios. Nominal limiting ratios range from 1.4 to 180, with the mean about 25. The 80% ratio ranges from 1.2 to 140, with the mean also about 25. The mean ratios correspond to reduction of 1/2- to 1/4-in. feeds to coarse flotation sizes or to a fine primary product in two-stage work. The high ratios represent one-stage grinds from 1-in. or coarser to flotation size and constitute about 20% of the whole.

Capacity. Controlling factors are discussed in Art. 14. Averages of the performance tables are graphed in Fig. 59, with ranges indicated by the verticals and the numbers of cases shown by the numerals adjacent to the range lines. With the exception of 2 of the

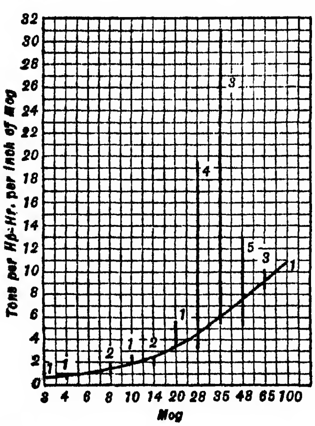

FIG. 59. Capacities of grate ball mills.

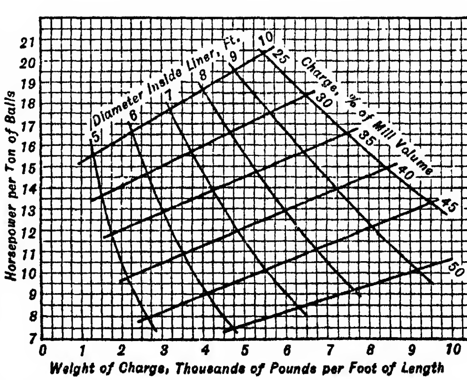

FIG. 60. Power consumption *vs.* charge volume in grate ball mills (averaged from Table 33; speed, 75 to 80% of critical).

values for 28 *mog*, 1 for 35 *mog*, and 1 for 48 *mog* the values cluster exceptionally close to the curve. For estimates apply the method of Art. 7 to Figs. 59 and 60. Capacity in tons per hr. per ton of charge through the normal reduction range averages about 2.6 in the range of 8 to 20 *mog* and 1.2 in the range of 28 to 65 *mog*. (See discussion under ***Capacity***, Art. 7.)

a Inside new liners.
b With allowance for shell liner.
c Numbers refer to lines in Table 33*a*.
e Estimated.
g Sec. 4, Art. 2.
h Art. 12. *CC* = closed circuit.
i *46 IMM 602.*
j Specific gravity.
k *Ed. 1.*
l 6 in. thick at crest of wave. Chilled cast iron at feed end with steel reinforcing bars cast in to prevent cracking as liners wear thin.
m Shell, 14 to 15 mo., 0.15 lb. per ton; feed end, 3 to 4 mo., 0.05 lb.
n Rolled chrome-steel bars with steel frame cast around; bolted Mn grates unsatisfactory on account of loosening.
o *IC 6544.*
p Closed circuit with a 3-mm. trommel.
q Screen analyses are for combined product of 1 @ 6 × 4 1/2-ft. mill and 4 @ 6 × 6-ft. mills in parallel.
r Average for 5 primary mills as per note *q*.
s See Table 47, Sec. 22.
t End liner, ribbed, Ni-Cr-Mo.
u *Bul. 34*[1] *CIMM 119.*
v *IC 6550.*
w Mn liner life: 3,939 hr., 42,000 tons of ore; Cr-Mo liner: 4,304 hr., 46,000 tons of ore.
x *IC 6605.*
y *IC 6555.*
z Shell, 3,200 hr., 0.273 lb. per ton; feed-end, 4,300 hr., 0.176 lb.; grate, 4,200 hr., 0.176 lb.
aa *40 CIMM 85.* See also Art. 4.
ab See Fig. 55.
ac See Art. 5.
ad *41 CIMM 286.*
ae Circumferentially grooved.
af Varies according to hardness of ore.
ag Cast, 3 1/2 in. thick, tangential slots flare to 5/8 in. Cleaning at 50-da. intervals requires about 3 1/2 hr.
ah All <1/2-in.; 30% <10-m.
ai 69% <200.
aj *IC 6759.* Oxide ore.
ak Underloaded.
al *IC 6753.* Sulphide ore.
am Including grate.
an *112 A 727.*
ao Weight shell liners new, 21,300 lb., life 160 da., scrap loss, 36%; feed-end liners, Mn, new weight 4,930 lb., life 190 da.
ap Weight, 3,440 lb.; life, 180 da.
aq Tempered to minimize breakage.
ar *IC 6550.*
as Forged steel and cast steel compared over a long period; cast steel cheaper.
at 28 t.p.h. if operated open-circuit, but then 2 @ 6 × 12-ft. secondary mills required instead of one with closed-circuit primary operation.
au 140 *#4 J 37.*
av Rounded nose; square nose gave too much lift.
aw Feed-throat and feed-end, 200 da.; discharge-end, 250 da.; shell, 365 da. Complete set weighs 43,100 lb. new.
ax Diam., 4 ft.; weight, 1,270 lb.
ay Total open area, 454 sq. in.
az The large mill is more efficient than two small mills of the same combined volume, which it replaced.
ba *A TP 1359.* Cement rock.
bb 90 tons when product desired is 75% <200-m.; 150 tons when 50% <200 satisfactory. For each per cent. reduction in $CaCO_3$ (and corresponding increase in percentage SiO_2) in feed, capacity falls approximately 2%. Can increase capacity by decreasing feed size.
bc New charge: 51% @ 4-in., 40% @ 3-in., 9% @ 2 1/2-in.
bd New charge: 2-in., 3.9%; 1 1/2, 18.1; 1 1/4, 26.0, 1, 26.0; 3/4, 26.0.
be Bowl sands from primary. See preceding column. One secondary to each primary. If feed is 90% $CaCO_3$ and primary product >48-m., the two secondaries will grind 150 t.p.h. to 96% <200-m.
bf Dumped every 4 mo. and charge brought back to original size composition.
bg Also nickel-bearing cast iron, with which consumption is 0.32 lb. per ton; scrap returned to foundry.
bh Liners and grates.
bi *134 A 344.*
bj Forged chrome-molybdenum steel.
bk 1 1/2 in. thick, taper 1/16 in. each side. Slots radial extending inward 13 in. from grate periphery to a blank center plate.
bl Heat-treated to 500 Brinell.
bm 187 tons total classifier sands per hr.; actual new sand feed unknown; may be estimated roughly from primary-classifier overflow (screen test *29*, Table 33*a*), which comprises feed to the secondary circuit, and overflow of bowl classifier, which is in circuit with this secondary mill.
bn Based on classifier overflow; actually larger than this against new mill feed.
bo Hard. Jig and table tailing, deslimed.

bp Appreciable amounts of pyrite.
bq Rad., radial slot; Tan, tangential slot; Sl, slotted, direction not known.
br Source of data for all columns headed only by designation of an ore is Mine & Smelter Supply Co. (*PC*).

bs

Mesh:	48	65	100	200	<200
% cum.	1.0	15.1	39.5	69.5	30.5

bt 21% >65-m.; 53% <200-m.
bu Primary jaw crusher product.

bv

Mesh:	150	200	<200
Cum. %	0.7	3.8	96.2

bw Very hard.
bx A secondary mill of the same specifications, in closed circuit with a bowl classifier, reduces the product further to 3.6% >150-m., 85% <200-m.
by One mill to 48 *mog*. See *bx*.
bz For two mills in series; see *bx*.
ca ⊙—2—1 *2*, 1 @ 16×20-ft. quadruplex; *3*, 1 @ 18-ft. bowl.
○—3—1
cb Total for 2 mills in series to 100 *mog* (see note *bx*).
cc With new liners.
cd New charge.
ce Varies according to setting of the reduction crushers.
cf About 70% <200-m.
cg New operation; not available.
ch 2 @ 54-in. duplex Akins classifiers per mill.
ci See also Gold Road, 5-82.

Charge volumes reported in Table 33 are definitely lower than are to be expected in grate mills, having the effect of lowering capacities and raising power consumption. The explanation probably lies in the fact that many of the data were reported during the "Roosevelt boom," when plants were running below capacity and ball charges were cut down to save power and to prevent overgrinding.

Power consumption for mills of different diameters at different charge volumes may be estimated from Fig. 60. Approximate relationships between power consumption and production are given in Fig. 61. In general, power consumption per ton of balls at 70 to 75% of critical speed lies between 10 and 15 hp., with higher figures corresponding to underloads of charge and/or rough liners, while lower figures are for smooth liners and/or relatively low speeds.

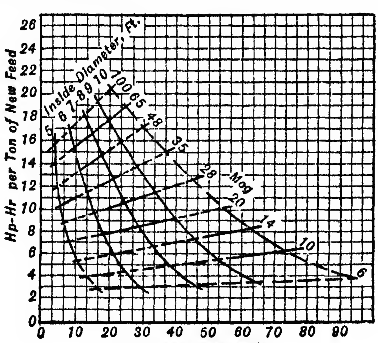

FIG. 61. Approximate relationship between power consumption, feed rate, and *mog* for grate ball mills.

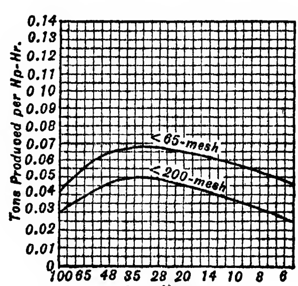

FIG. 62. Production of fine sizes in grate ball mills.

Efficiency. Tons per hp-hr., disregarding all other variables, average close to 0.13 for reduction to 35 *mog* and coarser and about 0.07 for 48 and 65 *mog*. Three markedly high figures in Table 33, corresponding to low reduction ratios, are excluded from these averages. Production of <65-m. and <200-m. material when grinding to different *mogs* is averaged in the graphs of Fig. 62. Spreads of ±50% of the graph averages are to be expected.

Speeds in Table 33 range from 62 to 87% of critical, with the greatest frequency apparently in the range of 75 to 79%, but actually probably in the range of 80 to 84%, since the percentages of critical were calculated on the basis of new liners of average thickness.

a Nominal.
b With allowance for shell liner.
c Numbers refer to lines in Table 34*a*.
d Sec. 4, Art. 2.
e Estimated.
f Art. 12.
g Closed by cone; tonnage not reported.
h Gr = grate; Ov = overflow.
i *41 CIMM 302.*
j 2 1/2-in. cast-iron, 0.48; 2-in. forged-steel, 1.22 lb.
k *20 CMI 98.*
l Mill discharge, 76% <200-m.; classifier overflow, 89% <325-m.
m *140 #4 J 39.*
n Average life, 654 da.; scrap loss, 13%; consumption about 0.25 lb. per ton.
o *42 IMM 207.*
p 40-lb. steel rail laid longitudinally with flanges covering joints in 1/2×4 1/2-in. plate grouted in. Rail held in by cast-iron chocks bolted through plates and shell. Life of rails 10 mo.; plates, 30 mo.
q Use of grates and concurrent head-end feed of pebble rock increased percentage of <200-m. in product to 78.
s Weight 7 to 16 lb. per piece.
t *IC 6553.* Limestone.
u *112 A 638, Q.*
v Circuit closed by classifier.
w 80% <325-m.
x 3/8-in. rd. holes, Mn; life 100 da.
y As *x*, but life 140 da.
aa Averages for 8 primary and 5 secondary mills.
ab 36% scrap included.
ac In a test run in which these mills were working in parallel on the same feed, the grate mill (open-end) produced 4.3 tons <200-m. per hr. from 7.6 tons of feed and the overflow mill produced 3.9 tons from 7.3 tons, corresponding to 0.025 and 0.020 ton per hp-hr. respectively (*41 CIMM 311*).
ad Apparently erroneous reports.
ae DF, Danish flint; HO, hard ore; for others see Table 47, Sec. 22.

Pulp density ranges from 70 to 85%, the higher figures corresponding to the coarser feeds and the greatest number of cases being in the 75-to-80 range. See also Art. 16.

Attendance. See Art. 18.

Lost time should not exceed 1%, to cover time for relining, except that if feed is too thick or the ore contains much wood, the grates will tend to blind and further time will be lost in more or less frequent cleaning. At SYLVANITE periodic (50-day) cleaning requires 3 1/2 hr.

Lubrication. See Art. 19.

Costs. See Art. 20.

Use. For discussion of grate-type *vs.* overflow-type mills see Art. 3.

Williamson mill has the end liners, or head-end liner and a grate, so conformed as to protrude three blunt plow-shaped wedges into the mill volume at each end. The wedge ridges are flush with the end at the trunnion rim, incline about 40 or 45° inward, and extend to the shell. The wedge angle is about 90°, and the leading face is so set, in effect, as to force a shovel under the end of the load at an angle as the mill revolves. The ridges at both ends lie in the same radial planes of the cylinder, so that the balls are poured out as through a converging shovel three times per revolution. The result is to add longitudinal travel to the load and to decrease the tendency for large balls to segregate against the ends. The speed recommended is lower than that for the usual cylindrical mill of the same diameter (*87 A 76*) owing to the increase in charge activity gained through the end conformation. For performance see the MIAMI flowsheet, Sec. 2, Fig. 22.

11. TUBE MILLS

Definition of this apparatus has never been precise. Modern practice tends to apply and confine the name to cylindrical mills with a length-diameter ratio greater than 2. The tumbling charge is usually balls or pebbles or a mixture thereof, but at many plants lumps of ore are substituted for pebbles, and, in a few, metal bodies such as punchings, small steel scrap, and the like are used.

Tube mills were the forerunners of center-discharge ball mills. They were adapted from cement practice into cyanide practice, and from cyaniding were taken over into concentration shortly before the adoption of flotation. They are used for finer grinding than ball mills. This end is accomplished by increasing length. Being used on finer feeds, diameter is reduced and lighter grinding media may be used. The STANDARD TUBE MILL, so-called because of its substantially uniform adoption in South African cyanide practice, is 5-ft. 6-in. diameter by 22-ft. length inside the shell. The modern development of the tube mill has been toward a shorter mill of somewhat greater diameter. This is a logical development of the more perfect methods of classification that have been developed. Originally it was necessary to finish the grinding in one passage through the mill. When this was done, great length was necessary, notwithstanding that the great bulk of the grinding was done in the first few feet of the mill. (See Fig. 9.)

a See p. 90.

Construction. SHELL is usually plate and heads cast. LININGS are plate, with or without lifters, or one of the many forms adapted to pick up and hold a part of the tumbling load. GRATES are common; aperture depends on grinding medium; for pebbles it is usually 1 to 1 1/2 in., for balls 3/16 to 1/4 in. inside, except that for very small balls (3/4-in. replacement) smaller apertures (3/32 to 1/8-in.) must be used to prevent excessive rejection. FEEDERS and arrangements of the discharge end are similar to those used with ball mills except that where rock is used as the tumbling medium special feed arrangements are used to handle the relatively large tonnages necessary and a trommel is often fitted to the discharge end to separate out the rock fragments which are crowded out. DRIVES are the same as for ball mills. For details see Art. 4. For setting instructions see Labbe (*101 J 777*).

Sizes most used are 5×16-, 5×22-, 6×22-, 7×24- and 8×26-ft.

Performance data are presented in Table 34. A summary of Rand performances is given in Tables 35 and 36 and in the following paragraph. See also the LAKE SHORE paper (*LS*).

a Mine-rock pebbles and steel balls or steel scrap.
b Selected mine rock.
c 1934.

Rand practice (after Prentice, *44 IMM 479*). The mills used range from 5 1/2 to 8 ft. in diameter and 22 to 16 ft. in length correspondingly. Substantially all use grates with elevators to trunnion discharges. Experience shows about 15% more grinding to <100-m. with grates, but power and liner and pebble consumption are also higher by about 15%. Grates are made 2 to 3 in. thick with slots to permit discharge of 1 1/2-in. pebble. Liners are universally of steel, of bar (Osborne) or block types (Art. 5). A typical Osborne liner has 4×1 1/4×3/4-in. steel bars alternating with end wedged in by flat bars 2 1/2 or 3 in. wide × 1/2 to 3/4 in. thick; total weight of steel for a 5 1/2×22-ft. mill is about 10 tons. Block liners are white-iron or steel castings, say 21 × 8 × 4 or 5 in. thick, either solid or honeycombed for pebble catch. The solid type is usually either waved or corrugated. Edges are ground to wedge in without bolting. Weight of solid blocks for a 5 1/2×22-ft. mill is about 13 tons. Life is 140 to 380 days. Charges are usually a composite of mine rock (2 1/2 parts) and balls or scrap steel (1 part), if the motors have sufficient power. Balls are usually 3-in. in primary mills and 2 1/2-in. in secondary. Cast balls cost (1934) $60 to $65 per ton. Scrap steel is ordinarily 4-in. lengths of

rail or about 4-lb. lumps of scrap liner; effectiveness in grinding is less than with balls, but cost is only about 10% of that of balls. Trunnion trommels with 1/4-in. aperture collect 2 to 40 tons of reject pebble per mill per 24 hr. Daily pebble consumption is about 13 tons in 5 1/2-ft. mills, 20 for 6-ft., 33 for 6 1/2-ft., and 55 for 8-ft. Motors for 5 1/2×22-ft. mills are 100 to 125-hp. for pebble loads; for composite loads: 175-hp. for 5 1/2-ft., 250-hp. for 6 1/2×20-ft., and 350-hp. for 8×16-ft. Feeds are <1-in. Pulp density is 67 to 75% solids. Capacity is about 450 tons total feed (new + circulating) per 24 hr. to a 5 1/2-ft. mill, 900 to a 6 1/2-ft., and 1,300 to an 8-ft.; circulating-load ratio is rarely greater than 2.0. Centrifugal pumps, air lifts, or hydraulic lifts are used for elevation to classifiers. Capacity rated on production of <100-m. is about 150 tons per 24 hr. for a 5 1/2-ft. mill with pebble load, and 230 tons for a 6 1/2×20-ft. mill; for a composite load the daily tonnage is about 15% greater at an increased cost per ton for the balls of 2¢. Power consumption averages 18 kw-hr. per ton of <100-m. produced. Average cost per ton of <100-m. produced (1934) was about 30¢ per ton in all-slime plants and 22¢ per ton in sand-slime plants.

At YOUNG-DAVIDSON (*Bul 333 CIMM 52*) when using a half-and-half load of flint pebbles and 2 1/2-in. balls, consumption was 0.4 lb. of balls and 0.5 lb. of pebbles per ton of new feed.

Size of feed in most modern practice, other than that prevailing in the Rand, is in the range of 14- or 20-m. limiting mesh, this material being prepared by a primary ball mill or by a preceding tube mill. Rand practice, in which considerably coarser feeds go to primary tube mills, is a survival stemming from adaptation of existing gravity-stamp tube-mill installations. The new plants on the Rand use secondary crushers, primary ball mills, and one or two stages of tube milling, according to the size necessary for reasonably complete exposure of values.

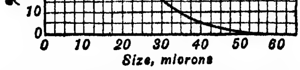

FIG. 63. Characteristic curve for fine tube milling; closed circuit; hard ore.

Within limits, the amount of fine material produced per mill per unit of time, particularly in single-pass grinding, increases with the size of feed. The general trend is shown in Table 34. The tendency is more pronounced with pebble charges than with balls, due to the fact that the heavier balls break down the coarse particles more readily than pebbles do, and the contribution to fines production from the surface irregularities of these large particles is not so great proportionately. (See also *Ed. 1, p. 451.*)

Size of product is generally 100 *mog* or finer. Distribution curve based on infrasizing (Sec. 19, Art. 14) is shown in Fig. 63.

Reduction ratios are, in general, less than 10. Higher ratios correspond to the outmoded practice of feeding 1/4-in. or coarser material.

Capacity to a given *mog* is dependent primarily upon kind and volume of tumbling charge and its activity. Mill diameter is of relatively small importance with ball charges because of fine feeds, but is important with pebble loads. Variations in capacity with optimum charge conditions are due almost entirely to ore character, *mog*, and pulp consistency. With average ores, 5- and 6-ft. mills charged with pebbles should grind about 0.3 to 0.4 ton per hour per ton of charge from 14~20-m. limiting to 100 *mog*; with ball charges production should average 50% higher. It is reported (*32 JCM 98*) that under similar conditions on Rand ore capacity decreases 10% for each increase of 5% in the amount of <200-m. in the product.

a Power constant throughout at 47 hp. in coarse-feed tests and at 44.8 hp. in fine-feed tests.

Character of ore has, in general, more to do with the grinding done in tube mills than in ball mills for the reason that tube-mill feed and product are normally both finer than ball-mill and the bulk of the work of the tube lies in grinding the ultimate crystals of the rock-forming minerals, while much of the work of the ball mill lies in breaking the rock along the parting surfaces between the crystals. Resistance to such parting is much the same in many rocks, hence the resistance of such rocks to ball-mill grinding is similar. But the ultimate mineral crystals differ widely in hardness and toughness and there is consequent variable resistance to grinding in the tube mill. Accurate data on this score, which will form a basis for comparison between plants, are substantially impossible to collect and present, but the possible differences in grinding resistance must be borne in mind in estimating capacity, and final estimates in important cases should always await the test of actual trial. See Tables 44 to 51.

Effect of feed rate in closed-circuit work is shown in Table 37.

Power consumption depends upon weight of charge, diameter of mill, speed, type of lining, and consistency of pulp. For estimates, an average figure of 6 to 7 hp. per ton of pebble load for a 5-ft. center-discharge mill with silex lining, loaded to the axis and grinding a pulp containing 35 to 40% water, is safe, if an additional allowance of 50% is made to cover starting overload. With a ball charge, wave or pocket liners, and 45 to 50% ball volume, 9 to 10 hp. per ton of charge should be estimated. See also Art. 15.

Efficiency. Tons per hp-hr. to 48 *mog* lies, in general, between 0.06 and 0.08 for average ores; the figure tends to be higher with pebble loading. In grinding to 100 or 150 *mog*, tons per hp-hr. will normally lie between 0.03 and 0.05 and tons <200-m. produced per hp-hr. in such grinding will range from 0.015 to 0.030. When grinding to 200-m. limiting the usual range of tons new feed per hp-hr. lies between 0.02 and 0.04, but the tons <200-m. produced per hp-hr. will usually not amount to more than 0.01 to 0.02.

Speed normally ranges from 75 to 85% of critical, the higher speeds corresponding to the smoother liners and smaller loads.

Pulp density is usually from 60 to 70% of solids with pebble charges and 70 to 75% with ball charges. See also Art. 16.

Attendance. See Art. 18.

Lost time. Table 35 indicates an average of about 2 to 5%. With ball charges, freedom from organic waste, a reasonably fluid pulp, and uniform feeding, it should not exceed 1%, principally for relining.

Lubrication. See Art. 19.

Costs. See Art. 20.

OPERATION OF TUMBLING MILLS

[For SPEED see Art. 2; HEIGHT OF DISCHARGE, Art. 3; LINERS and LINER CONSUMPTION, Art. 5; TUMBLING MEDIA, rationing and consumption, Art. 6.]

12. CLOSED-CIRCUIT OPERATION

The practice of discharging partly finished pulp from a mill, removing the finished portion and returning the balance has become an essential part of fine-grinding practice and increasingly an element of coarse grinding. Both screens and sedimentation-type sand-slime separators have been used to remove the fines (CLOSE THE CIRCUIT); mechanical classifiers predominate overwhelmingly. There is no doubt that initially this predominance was due, in part, to the ability of the mechanical classifier to elevate the separated coarse material sufficiently for gravity return to the mill; nowadays this is no longer true of the big classifiers, and auxiliary elevating means must be employed. But ease of operation, relatively satisfactory size-separation, and selective return of metalliferous mineral and middling for finer grinding more than justify its retention.

For description of classifiers and their operation see Sec. 8; for screens, Sec. 7.

Open *vs.* closed circuit. The superiority of closed-circuit operation in finishing grinding in ore milling has been so apparent that few of the results proving it have been published.

Dorr and Anable (*112 A 161*) assert that at LAKE SHORE closure increased the tonnage of finished material per mill 45%, reduced steel consumption from 6.5 lb. per ton of new feed to 3.2 lb., and decreased power consumption 10%, probably because the increased throughput moved the center of gravity of the total load nearer the center of rotation; this reduction constituted a 37% drop per ton of finished material. At LUCKY TIGER (*Ed. 1*) a 5×14-ft. mill grinding 6 or 10-m. feed to 100 *mog* had a daily capacity of 22 tons in open circuit and 37 tons in closed circuit, the corresponding tons of <100-m. produced per hp-hr. being 0.016 and 0.055. A 6×20-ft. mill (*ibid.*) ground 144 tons per 24 hr. from 6-m. to 48 *mog* in open circuit and 240 tons in closed circuit.

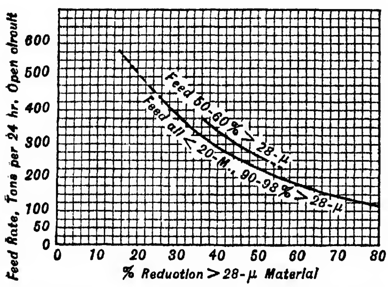
Improvement in primary-mill operation is less marked. At CANANEA (Dyrenforth and McArthur, *87 A 149*) closed-circuit operation produced 58% more <48-m. and 63% more <200-m. with 28% less power per ton of new feed and 36% reduction in steel consumption; at MIAMI (*ibid.*) partial closure of the primary circuit resulted in 10% increase in production of both <48-m. and <200-m. At CANANEA (*126 J 990*), in parallel operation of open-circuit and closed-circuit primary rod mills to 14 *mog*, with equal tonnages to both mills, there was 7% less >20-m., 11% more >48-m., and 7% less <200-m. in the closed-circuit product, equivalent to a saving of about 3¢ per ton milled. At BRADEN (Table 41) circuit closure on a primary rod mill increased the production of <100-m. material from the same new feed 21%. Closing the circuit on the primary mill at CONSOL. MG. & SM. CO. (*32[1] CIMM 173*) increased grinding 20 to 25%. C. F. Thompson (*PC*) states that use of even small classifiers on primary mills raises capacity in a stage-grinding circuit by 15 to as much as 50%, the more the harder the ore.

Circuit closure increases selective grinding of grains containing heavy mineral; when this is the valuable mineral a coarser over-all grind is thus made possible. At MIAMI (*87 A 149*) the increase in assay of bowl-classifier sands over that of the overflow (circuit feed) was about 25% in the 48-m. size, 40% in the 65-, and 50% in the 100-, 150-, and 200-m. sizes, while the <200-m. material assayed substantially the same in both products. At UNITED VERDE (*87 A 146*), with 39% sulphides in the primary feed there was 55% in the primary rake-classifier sands and 53% in the bowl sands in the secondary circuit. Marked concentration is reported in Rand circuits. Presence of flotation collector in the grinding circuit decreases selective grinding of sulphides. Selective grinding is advantageous in cyanide mills, but it may produce overgrinding of sulphides in flotation mills.

Causes of advantage in closed-circuit grinding. The changes in conditions inside a mill which correlate with its improved performance in closed circuit, and which must, therefore, hold the key to the explanation, are: (1) Reduction in mean size of feed; (2) marked increase in near-finished sizes; (3) marked decrease in proportion of finished sizes; (4) more rapid travel, *i.e.*, a shorter time per pass; (5) closer approach to a uniform ratio of

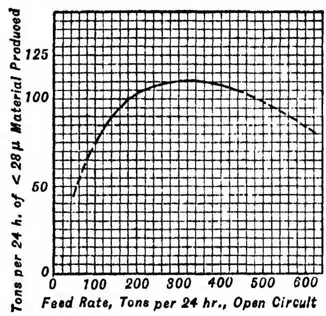
ball size to average particle size throughout the length; (6) some increase in quantity of interstitial pulp. The most probable major causes of the improvement are (2), (4), and (5).

Near-finished feed. In cascading operation on fine feeds a mill operates most effectively, all other things being equal, when the ratio of ball size to particle size is such that nip angles with balls in contact are 20° or less (see Fig. 23). Capacity increases with decreasing diameter of ball to the point



30 r.p.m., 3/4-in. balls, 45% charge, 1 1/4-in. liners.

FIG. 64. Performance curve for 5 ×16-ft. overflow-type tube mill at LAKE SHORE.



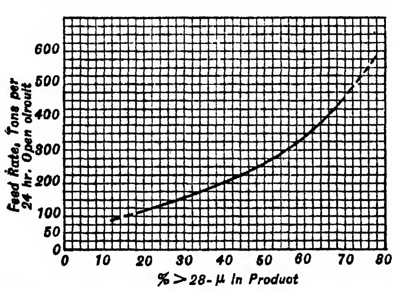
30 r.p.m., 3/4-in. balls, 45% charge, 1 1/4-in. liners, feed <20-m. sand.

FIG. 65. Production of 28-μ material in 5 ×16-ft. overflow-type tube mill at LAKE SHORE.

that nip angle exceeds the above figure. Consequently the more near-finished material there is in the feed, the higher the proportion of favorable nip angles, and the finer the mean feed the smaller the mean ball diameter may be. Thus in Fig. 64, the reduction of >28-μ material is increased 18% at 300 tons per day feed rate by the decrease in mean size of >28-μ feed as between 90% >28-μ and 50% >28-μ.

The presence of this extra amount of fine sand with coarse particles of new feed has the further effect of increasing the allowable nip angle for the coarse particles. The fine material sands the track, as it were (Sec. 4, Art. 8), and also, by packing around the coarse particles in the interstices of the load, resists their tendency to recede from the crushing zone when nip is difficult.

Uniformity of distribution of feed-size material throughout the mill is evidenced by the relatively small differences in sizing analyses between feed and product, particularly in mills carrying high circulating loads (see Tables 24*a*, 30*a*, 32*a*, 33*a*, and 34*a*). The relative effectiveness of the tumbling



30 r.p.m., 3/4-in. balls, 45% charge, 1 1/4-in. liners.

FIG. 66. Size of product *vs.* feed rate; 5 ×16-ft. overflow-type tube mill at LAKE SHORE.

load on new feed and more or less reduced material is clearly shown in Fig. 9. This is operation of the familiar law of diminishing returns. The same phenomenon with a different incidence is shown in Table 38 for relatively coarse feeds and in Figs. 64, 65, and 66 for fine feeds. Fig. 65 shows also that the increase in production with increase in feed rate does have an end well short of the breakdown of grinding in the mill, *i.e.*, that substantially optimum load conditions extend over a considerable part of the range of effective grinding. By increasing feed rate and correspondingly increasing flow through the mill and decreasing the time spent by the pulp at each point along the length, pulp is caused to arrive at each point in the mill and even at the discharge end in substantially the same favorable state for reduction that it entered, with the result that the high reduction rate that prevails in the feed end persists with little diminution throughout.

Reduction in the proportion of finished sizes in the mill reduces overgrinding; this in turn increases the energy available for useful grinding so long as there is an ample supply of unfinished material present.

Gow *et al.* (*112 A 59*) showed the analogy between overgrinding in open circuit or with low circulating ratio and roll operation. They ran a test on rolls in which 40 stages were used to reduce to 48 *mog*. The product contained 22% <200-m. Choke crushing to the same *mog* produced 72% <200-m. To approach the granular product by ball milling would require a short mill, high circulating load, and substantially perfect size separation. Decrease in the amount of <200-m. produced increased the amount of intermediate sizes in the product.

The greater quantity of interstitial material present in a mill operating in closed circuit decreases the effectiveness of the tumbling load to the extent that it exceeds the interstitial volume available with the tumbling media in substantial contact. This is due to the so-called CUSHIONING EFFECT, *i.e.*, distribution of pressure to the point of diffusion. On the other hand, such spreading of the load decreases power and steel consumption, so that the net effect, if the spreading is not excessive, is an increase in operating-cost efficiency.

Table 39. Effect of change in circulating load on capacity of a 6×10-ft. ball mill grinding to 20 *mog* in circuit with an 8×27-ft. heavy-duty classifier (*After McArthur, 134 A 277*)

<200	38.8		49.7		

Circulating load is the tonnage of solid returned to the mill by the circuit-closing apparatus. It is expressed either as a percentage of new-feed tonnage or as a ratio of circulating tonnage to the tonnage of new feed taken as 1. Circulating loads in practice range from percentages as low as 25 to as high as 1,800.

Tonnage of circulating load is as it falls as a result of physical integration of the reduction ability of the mill on the particular feed running, the tonnage of new feed and its size, the size at which the circuit-closing apparatus is set to discharge, and the separating efficiency of this apparatus. All other things being in each case equal, circulating load is increased by increase in average size of new feed, tonnage of new feed, resistance of new feed to reduction, and by decrease in limiting size of product or of the efficiency of the mill. Throughput corresponding to a given circulating load increases with softness of the new feed.

Table 40. Effect of feed rate on circulating load in open-end ball mill at International Nickel (*58 CMJ 665*)

200	43.5	43.2	38.7	43.6
<200	56.5	56.8	61.3	56.4

NOTE. Mill operating at 23 1/2 r.p.m. and drawing 200 hp. Feed all <3/8-in.

Within limits, the larger the circulating load the greater the useful capacity of a mill. This is shown clearly by Tables 39 and 40. Increase is most rapid in the first 100% of circulating load, but continues at a material rate thereafter up to some limit, dependent upon the particular circuit, shortly beyond which the circuit chokes.

Fig. 67 presents the results of test work in a 3-ft. laboratory mill, taking <3/8-in. limestone feed. It will be noted that circuit capacity was still rising at 500% circulation. Table 41 shows the same trend in plant practice, with effective circulating loads increasing up to 800%. Dorr and Anable (*134 A 168*) are authority for the statement that circulating loads of over 1,800% have been carried successfully. On the basis of small-mill tests, Bond and Maxson (*134 A 315*) conclude that production to a desired *mog* increases rapidly with increase in circulating load to a broad maximum that is substantially asymptotic between the critical or first marked inflection point and a drop just prior to choking. The Lake Shore tests indicated that substantially the maximum aid from recirculation is reached in fine grinding between 250 and 350% of circulating load. The data of Table 41, however, are generally characteristic of mill experience, and when plotted indicate a gradual but consistent rise in capacity to a given *mog*, at a gradually decreasing rate, with a relatively sudden final drop indicating the onset of choking.

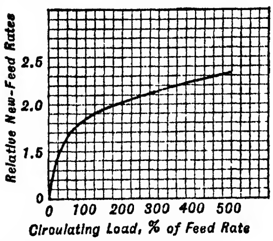

Fig. 67. Change in circuit capacity with change in circulating load (*after Davis*).

Increase in capacity due to circuit closure and/or to increases in circulating load is accompanied by decrease in fineness of the product passing the limiting product screen. This follows from the fact that power input is substantially unaffected by mill throughput and that the total mill work is simply differently distributed as throughput varies.

Table 41. Changes in capacity of grinding mills with changes in total mill load, Braden Copper Co. (*After McArthur, 134 A 277*)

Grinding mill	Tumbling medium	Classifiers in circuit	New feed, tons per 24 hr.	Circulating load		Total tons solid through mill per 24 hr. per cu. ft. of nominal mill volume	Tons <100-m. produced per 24 hr. per mill
				Tons per 24 hr.	%		
1 @ 8×12-ft. primary	Rods	None	1,238	....	0	2	314

a New feed to bowl. *b* 1 bowl to 2 mills in parallel.

McArthur (*134 A 274*) takes the position that the essential element in considering circulating load is the mill throughput and that this is measurable relatively as tons of dry feed per 24 hr. per cu. ft. of nominal mill volume. A column of such figures is given in Table 41. McArthur asserts that modern practice with large mills and heavy-duty classifiers (Sec. 8) clusters in the range of 14 to 20 tons per 24 hr. per cu. ft. of mill volume although the circulating loads in the same circuits range from 400 to 900%. He states that one mill has done well with a throughput of 30 tons per cu. ft. Rose (*134 A 361*) sets the allowable daily throughput at 9 to 14 tons in grinding to 48 or 65 *mog*. McArthur recommends installation of a ball-retaining grid for overflow mills when running high circulating loads. Such a grid used at Hollinger is shown in Fig. 68.

Coghill and deVaney (*CEG*) use tons composite feed per hp-hr. as a measure of the relative size of a circulating load, on the basis, presumably, that comparison of this figure with the tons per hp-hr. to finishing mesh indicates the extent of reduction per pass. They point out that at Hollinger the composite-feed throughput is 0.9 ton per hp-hr. (1.25 min. per pass), which they characterize as a record for mild treatment. The production of <48-m. at Hollinger under the above conditions (*134 A 331*) was 0.1 ton per hp-hr. These authors point out the possibility of increasing the Hollinger rate by using a shorter mill—the mill was already open-end with a full grate—and suggest that on soft ores in such a mill total load might well run up to 2 tons per hp-hr. as against 0.5 ton for hard ores.

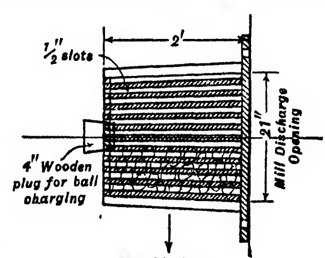

Fig. 68. Ball-retaining grid on 6×14 1/2-ft. overflow mill at Hollinger (*after H. W. Hitzrot, PC*).

Coghill and deVaney (*27 #6 MMC 7*) summarize the effects of variation in circulating load on size of circuit products as follows: As tonnage of new feed increases and the tonnage of classifier sands correspondingly grows, the classifier sands become coarser, but the composite mill feed becomes finer because of the higher content of circulating load. At the same time the mill discharge becomes coarser because of decreased time-per-pass, so that the spread in size between composite feed and mill discharge decreases. They assert that the amount ground out per pass varies as the arithmetic mean of the surfaces (Coghill method, Sec. 19, Art. 19) of composite feed and mill discharge, and that the capacity of the circuit varies inversely as the percentage of finished material in the composite feed.

Balanced circuit. Conditions for a grinding circuit in balance are given in the following equations. Let T = tons per unit of time of the material indicated by its subscripts. Subscripts: C = composite feed, N = new feed, R = return sand; O = oversize, and U= undersize of the separating mesh; G denotes ground through separating mesh. C = circulating-load ratio, f = decimal fraction (cumulative) of new feed retained on separating mesh, and g = decimal fraction of composite feed ground through separating mesh per unit of time.

$$T_{RO} = T_{CO} - T_G \qquad (1)$$

$$T_{CO} = T_{RO} + T_{NO} \qquad (2)$$

From (1) and (2)

$$T_G = T_{NO} \qquad (3)$$

By definition:

$$\frac{T_R}{T_N} = C \qquad (4)$$

$$g = \frac{T_G}{T_C} \qquad (5)$$

$$T_C = T_R + T_N \qquad (6)$$

From (3), (4), (5), and (6)

$$g = \frac{T_{NO}}{T_R} \cdot \frac{C}{1 + C} \qquad (7)$$

$$f = \frac{T_{NO}}{T_N} \qquad (8)$$

From (7), (8), and (4)

$$g = \frac{f}{1 + C} \qquad (9)$$

Since (9) is true for the cumulative oversize on the separating screen and for any tonnage and time, it must be true for each of the corresponding cumulative oversizes coarser than the separating screen. Further, if it is true for the cumulative oversizes, it must be true for the individual overssize. Now $1 + C$ is the number of passes through the mill assured to any given particle of oversize in new feed. Hence g is the fractional part of each and every individual oversize in the new feed, above and including the separating screen, that must be ground through that screen per pass, in order to maintain the circuit in balance.

New-feed rate. Unless the new feed is completely uniform in size distribution, quantity, and crushing resistance, and the separation by the circuit-closing apparatus (GUARD) a constant, or unless the variation in one of these factors is automatically compensated by variations in one or more of the others, which is even less within the realm of likelihood, then new mill-feed tonnage must follow a roughly sinusoidal path, with control following some indicator of the feed-discharge oversize ratio. Mill sound and mill power draft are the operating indicators (see Art. 18). Tendency for material to build up at a given size may be countered by change in the ball ration (Art. 6). Thus at NEW CORNELIA (*143 #5 J 63*) build-up of 35∼65-m. material in grinding to 65 *mog* was overcome by changing the new-ball feed from 100% @ 3-in. to 40 @ 3-in. and 60 @ 2-in.

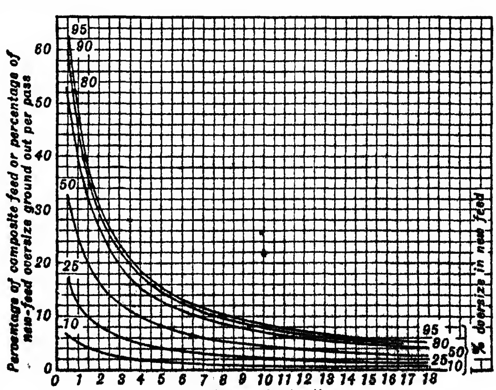

FIG. 69. Grind-per-pass vs. circulating load.

Severity of grind necessary to maintain balance with different amounts of finished undersize in new feed is indicated in Fig. 69. It is apparent that with new feeds containing large percentages of unfinished material the percentage ground out per pass must be large with low circulating-load ratios, but that the advantage of increase

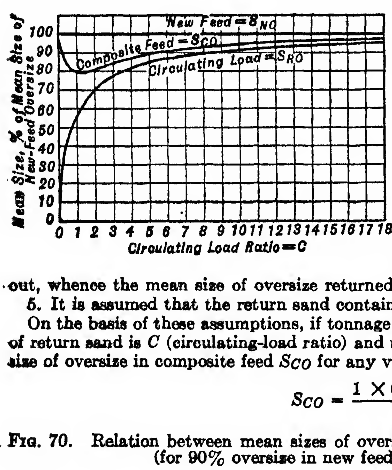
in ratio beyond 5 or 6 is relatively small. With high percentages of finished material in the feed, on the other hand, there is little advantage in ratios larger than 2 or 3.

Point of introduction of circuit feed. It appears from the preceding paragraph that little advantage is gained as respects severity of grind by closing a grinding circuit, if the new feed to the mill already contains considerable amounts of finished material. But if this material is first removed, as by a preliminary classifier, or introduction of new feed to the classifier closing the circuit, the new feed is changed in nature to one in which the percentage of oversize is large, and circulating-load ratios of 5 or 6 become economical.

Exhaustive tests at INTERNATIONAL NICKEL (*58 CMJ 665*) indicated that there was no mechanical nor metallurgical difference between introducing 4-in. feed directly to rod mills or into the classifier. On the other hand, at BALMAT (*IC 6574*) change from introduction of <1/2-in. feed into classifier to introduction into the rod mill improved classifier efficiency and decreased steel consumption by 0.4 lb. per ton and caused an increase in circulating load from 192 to 207%.

Efficiency of circuit guard. Fig. 69 shows that since inefficiency of the guard increases circulating load, the effect on reduction of oversize is rapid decrease in percentage ground out per pass with circulating ratios of 5 or 6 or less. With larger ratios the effects of inefficiency are less prominent.

Optimum circulating load is not a matter to be decided on the basis of any one consideration. Ultimately it should come down to a question of economics in which the factors are metallurgy, market demand (both price and quantity), and cost (both operating and overhead). The mean size of the finished product with a fixed percentage on the



Notes to Fig. 70. The calculations underlying this figure involve a number of assumptions. It is believed, nevertheless, that the relationship presented is real.

1. The mean size of the oversize in new feed S_{NO} = 1.0. Percentage oversize is taken as 90.
2. It is assumed that the circuit guard has sufficient capacity so that the limiting size of separation and the separating efficiency remain constant.
3. It is assumed that the 90% curve in Fig. 69 is correct.
4. It is assumed that the reduction in mean size of oversize per pass is equal to the percentage ground out, whence the mean size of oversize returned, $S_{RO} = 1 - g$ (Fig. 69).
5. It is assumed that the return sand contains 35% undersize of the limiting mesh of separation.

On the basis of these assumptions, if tonnage of new feed is taken as 1.0, the corresponding tonnage of return sand is C (circulating-load ratio) and the tonnage of oversize in return sand is $0.65C$. Mean size of oversize in composite feed S_{CO} for any value of C is, therefore,

$$S_{CO} = \frac{1 \times 0.9 + 0.65C(1 - g)}{0.9 + 0.65C}$$

FIG. 70. Relation between mean sizes of oversize in new feed, circulating load, and composite feed (for 90% oversize in new feed and 35% undersize in sand return).

mog increases with increase in circulating-load ratio. This normally correlates with decreased liberation, and corresponding decrease in grade of concentrate or of recovery or both. On the other hand, increase in circulating load was used at HARD ROCK (*34 CIMM 206*) to decrease sliming and overgrinding, which had the effect of bettering flotation results. Net capacity of the circuit increases with increase in circulating-load ratio, provided there is not a corresponding increase in undersize return; this tends to decrease operating and power costs, and to offset losses in metallurgy. Market is an independent factor to the extent that a high-price market with unlimited quantity demand may show increased profits at high tonnages even though these result in both inefficient grinding and poor metallurgy.

When efficient grinding is the primary end sought, optimum circulating load is probably that which gives the largest composite load consistent with a mean size of composite oversize near the minimum. On Fig. 70 this would be between 200 and 300% circulating load. This follows from the fact that the smaller the range between maximum size of feed and finishing size, the less the reduction necessary, the higher the capacity, and the more closely the size of tumbling medium can be rationed (Art. 6).

Circulating load is normally larger in fine-grinding and in secondary circuits than in corresponding coarser circuits. Because of the tendency of sulphides to build up circulation, the load with heavy sulphide ores tends to be larger than under corresponding conditions with low sulphide ores.

Large circulating loads are advantageous in compensating for fluctuations in new-feed size.

Gow *et al.* (*loc. cit.*) set down as criteria for good closed-circuit practice: (1) a moderate mean-mesh reduction ratio (Sec. 19, Art. 19), say 2 to 4, and (2) a limiting size of classifier sand not too far from the limiting size of new feed (say one-half).

Estimate of circulating load may be made by application of the recovery formula (Sec. 19, Art. 24) to the sizing tests of feed and products of the circuit guard, knowing that tonnage of overflow equals tonnage of new feed. It is found that the tonnage thus estimated varies considerably according to the size taken as the assay basis. This size should be the one for which the least assay value is the largest number. The only reliable determination of circulating load is by a tonnage sample, either of the load itself or by separate tonnage measurements on new feed to the circuit and total circuit flow.

Interstitial filling. Visualization of physical conditions in a tumbling load (Art. 2) indicates that maximum availability of grindable material to active grinding zones occurs when the grinding faces are in substantial contact and the interstices are completely filled with a pulp as thick as will permit ready flow. Batch testing (*CEG*) shows that both maximum power draft and maximum grinding occur at this condition; it is indicated, however, that maximum power efficiency occurs with a greater interstitial loading, because of the fact that grinding per unit of pulp charge does not decrease in the early stages of crowding expansion of the tumbling charge as fast as power does.

The principal factor controlling interstitial charge in continuous operation is height of discharge. Feed rate and pulp consistency have minor effects, increasing with height of discharge. Decrease in tumbling load with a high-discharge mill aggravates the condition of a pool of pulp above the toe, in which, of course, no grinding is done and the contained material is statistically not in the grinding mill at all. High sp. gr. of material being ground, low sp. gr. of tumbling media, and great length all increase interstitial charge.

Batch laboratory tests (*CEG*) with different minerals, different interstitial loadings, and different speeds indicated that grinding efficiency is a function of all three of these variables. Efficiency was maximum for heavy loads of both chert and dolomite at about 50% of critical speed; with small charges, the efficiency with chert was substantially unaffected by speed, but with dolomite it increased with speed.

Circuit guard may be a screen, a classifier, a concentrating circuit, or any combination of these. Use of mechanical classifiers predominates overwhelmingly. Exhaustive tests with vibrating screens were made at INTERNATIONAL NICKEL (*134 A 361*), indicating that, using stainless-steel cloth, capital cost, repairs, and power consumption would be less than for rake classifiers of equally large capacity, while operating labor would be about the same in the two cases. The screen fails, however, to cause selective grinding of sulphides, and loses out, therefore, on a metallurgical basis in a sulphide-flotation or hydrometallurgical plant; it has shown an advantage in gravity concentration (ARAMAYO, cassiterite; MAGMA, Flat River), some nonmetallic flotation (ALUMINUM ORE CO., fluorspar), and in wet magnetic concentration (TITANIUM PRODUCTS CO., Sec. 2, Fig. 159).

Playford (*91 NS Aa 439*) states that at MT. LYELL the volume of the chalcopyrite particles in the overflow of a primary classifier at sp. gr. = 1.71 was $1/_{31}$ of the volume of the accompanying quartz particles, and that when the overflow was 1.25 sp. gr. the corresponding fraction was $1/_8$.

Ordinary iron screens rust so rapidly in wet circuits and consequently blind and wear to such an extent as to be useless; at ALUMINUM ORE CO. (*134 A 322*) where 60×42-m. cloth was used for 65-m. separation in the regular operation of the grinding circuit, much trouble with blinding occurred, which was alleviated by use of stainless steel. Price of stainless-steel cloth is about 3 times that of phosphor bronze; Monel metal has not the abrasion resistance of stainless steel and price is within 10% of it.

Classifier capacity. Until recent years lack of classifier capacity has limited circulating loads in many mills, and has thus limited grinding capacity.

At TOUGH OAKES capacity with two classifiers was 28% greater than with one; at CONSOLIDATED MIN. & SMELTING, 35%; at WRIGHT-HARGREAVES increase in size of classifier increased tonnage to 20 *mog* 45%, and at MORENCI a similar change produced an increase of 96% to 65 *mog*; at CHINO, in a test run, change from one classifier per mill to six resulted in change in circuit capacity from 150 to 250 tons per 24 hr. and in reduction of steel consumption from 3.2 to 1.5 lb. per ton of new feed (*112 A 161*). At BLACK HAWK (*IC 6359*) change from a small to a large classifier decreased total mill cost from \$1.85 or \$2.00 per ton to \$1.50 or \$1.65 per ton. At EL POTOSI (*PC*) the limiting capacity of a circuit with a 5×12-ft. rod mill and an old-style classifier was 16 t.p.h. grinding from $1/_2$-in. to 28 *mog*; installation of a large heavy-duty classifier permitted increase in circulating load, and capacity of the circuit was raised to 20 t.p.h. without change in *mog*. Performance figures on grinding-mill capacities with old-style classifiers must, therefore, be read with these facts in mind. Continuation of the inefficient circuits was due to the necessity for large floor space and auxiliary transport that was involved in multiplication of classifiers. Heavy-duty mechanical classifiers (Sec. 8) are now available, however, with capacity sufficient to swamp any available single grinding unit.

Concentrators in the grinding circuit save mineral at relatively coarse sizes and thus insure against after loss; they reduce both the tonnage to be ground and the tonnage of circulating load. Their use in primary circuits in gold-flotation mills is almost standard practice (see Sec. 2, Art. 22).

At HARD ROCK (*34 CIMM 206*), a unit flotation cell placed in the circuit removed about 50% of the sulphides and permitted an increase in the new feed to a 7×9-ft. ball mill from 12.6 to 14.7 t.p.h. with a reduction in circulating-load ratio from 6 to 4.5. Parsons (*60 CMJ 693*) notes the revival of AMALGAMATION for this service; he calls attention to the tendency of ball mills to flatten gold and make it unsuitable for concentration on amalgamating plates, wherefore jigs or blanket tables are better. A mill modification of the superpanner (Sec. 19, Art. 22) is said to be having considerable success; in some cases the sides of the bowl are amalgamated. White (*31 JCM 161*) states that inclusion of amalgamation in the grinding circuit results in a tremendous tie-up of gold in the grinding mill. Table 42 presents the distribution of such values in the clean-up of one mill with El Oro lining. This tie-up is less, of course, when grinding in cyanide solution. The effect of stopping a mill is to cause discharge of enriched pulp on restarting. Thus a mill which was averaging 9 dwt. discharge at 270 tons per 24 hr. discharged pulp assaying 325 dwt. immediately on restarting, 196 dwt. at 5 min. after starting, 87 dwt. at 10 min., 64 at 15, 58 at 25, 112 at 35, 96 at 45, 17 at 75, and averaged 10 for the 6-hr. period after starting. Full discharge rate of 270 tons was reached at 165 min. after starting. These data were confirmed by Dewar (*31 JCM 294*) at GOVERNMENT AREAS. He found, however, that gold released on a shutdown was substantially all picked up by corduroy, so that there was no undue fluctuation in feed to cyanidation. He also found a much smaller absorption by wave-type liners and a large absorption by a circuit including a rake classifier.

Table 42. Distribution of gold contents of a standard tube mill on renewal of liner after 192 days of operation

	Tons solid	Assay, oz. Au per ton	Oz. Au
Washed out by feeding water only with mill operating, 60 min.	3.74	3.55	13
Water stopped and mill run 20 min., when discharge stopped	0.40	11.05	5
Door plug opened and pulp charge flushed out	2.59	28.40	73
Washings from removed rail liners	0.50	402.1	202
Sand held back by rails before removal	0.32	174.8	55
Scrapings from mill shell	0.81	825.5	662
Scrapings from end liners and discharge grate	0.03	305.4	9
Totals *a*	8.39	121.4	1,019

a The calculated lockup at this time was 1,760 oz.

Roughing flotation of primary-circuit product with immediate discharge of tailing and regrind of rougher concentrate is practiced at a number of copper mills and at CLIMAX MOLYBDENUM (Sec. 2).

Concentrators in a grinding circuit, particularly flotation cells, are usually guarded against oversize by a screen. This is normally of trommel type attached to the discharge trunnion. It may be provided with an interior spiral for return of coarsest oversize and small balls. At the LAVA CAP mill (*140 #7 J 52*) the usual trunnion screen gave trouble because of the necessity to shut down the mill whenever screen repair was necessary. It was replaced by a vibrating screen, fed by a rotary elevator 76 in. diameter, with a bypass to the classifier to permit screen repair during operation. Elevator buckets were especially designed to operate at mill speed of 25 r.p.m. without centrifugal spill on the upcoming side or centrifugal carry-over at the top. Plan of the arrangement is shown in Fig. 71.

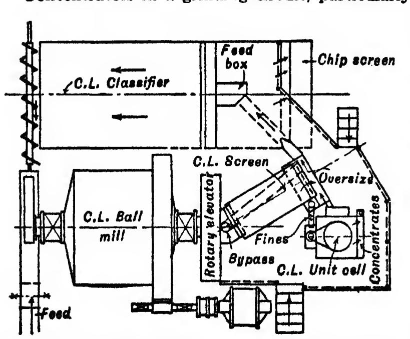


FIG. 71. Arrangement of scalping screen in grinding circuit at LAVA CAP.

As a general rule, if it is necessary to have auxiliary elevation in a grinding circuit, it is best to put it on the mill discharge; it is more dilute and easier to handle than return sand, and is less abrasive (*112 A 176*).

Differential grinding of materials of different hardnesses and substantially the same specific gravities causes concentration of the harder material in the circulating load.

At PERMANENTE (*148 A 374*) the primary-circuit feed contained 71% $CaCO_3$ in the >1/2-in. size and 88% in the >20-μ size; the mill discharge assayed 34% $CaCO_3$ in the >6-m. size and 85% at

>10-μ; classifier sands analyzed 48% $CaCO_3$ in the >6-m. size and 84% at >10-μ; classifier overflow contained 60% $CaCO_3$ in the >28-m. and 85% at >10-μ.

Differential grinding may be used as a preliminary step in concentration by choosing mill diameter and/or grinding media of such sizes that the soft ingredient of an ore is ground preferentially. Coghill and deVaney (*CEG*) cite oolitic hematite and quartz, barite and chert, and vanadium ore. Sphalerite in chert chats has been freed similarly, and the method was used on telluride dumps at INDEPENDENCE (*87 A 94*). See also Sec. 14, Art. 11.

Stage grinding is size reduction in a series of grinding circuits to which the feeds are successively finer. In the majority of cases two stages only are employed. Gow *et al.* (*loc. cit.*) define the term more broadly and include progressive reduction in a closed circuit, but this is not the usual connotation of the term.

Employment of stage grinding is based on what appears to be almost universal experience that greater economy in grinding ensues, if the reduction ratio in a single circuit is limited.

Limiting reduction ratios of 250 (3-in. to 48-m.) in a single stage were not uncommon 20 years ago. Modern practice inclines toward ratios of not to exceed 6 or 10 in primary and secondary mills and 4 or 6 in tertiary. The necessity for stage grinding increases and economical reduction per stage decreases with increasing resistance of the ore to grinding. The apparent reason is that best results in grinding are obtained when ball diameter is rationed to the near-finished size. If maximum size is too much larger than this, the large particles are not nipped unless the tumbling load is expanded by increasing interstitial filling. This decreases capacity. The alternative is to run at cataracting speeds in order to crush the large particles by impact, but this decreases superincumbent load, with a consequent decrease of cascade grinding that is not always fully compensated for by the increase therein due to higher rotation speeds of the tumbling bodies (Art. 2).

At UNITED VERDE (*IC 6343*), in a one-stage ball-mill operation, 1,200 tons per 24 hr. was ground to produce 840 tons of <100-m. at 15.3 hp-hr. per ton of <100-m. produced; in two-stage ball milling of the same feed 1,600 tons per 24 hr. was ground, producing 1,200 tons of <100-m. with a consumption of 14.2 hp-hr. per ton of <100-m. produced. Dorr and Marriott (*87 A 112*) reported that at UTAH (Arthur plant) change from one-stage to two-stage operation increased power consumed per ton milled from 5.9 to 7.6 hp-hr., but the grind was sufficiently finer so that the consumption per ton of <100-m. produced decreased from 15.6 to 14.4 hp-hr., and the corresponding figures for <200-m. were 21.8 and 19.8 hp-hr. Grade of concentrate was raised from 31% Cu to 32%, tailing fell from 0.19% Cu to 0.11%, and recovery increased from 81.7 to 89.3%. On the other hand, at ROAN ANTELOPE, with a relatively soft ore that classifies well, two @ 9×8-ft. grate mills per section in a two-stage arrangement thus: 1 @ 9×8-ft. ball mill → 1 @ 12×20-ft. quadruplex Dorr classifier, sands to mill, → 2 @ 18 (diam.)×12×31 2/3-ft. bowl classifiers in parallel, overflow finished, → 1 @ 9×8-ft. ball mill, discharge to bowls, ground 1,500 to 1,600 tons per 24 hr. from 1 1/2-in. to 86% <200-m. (100 *mog*). Difficulty was had in maintaining balance between the circuits, and the bowls tended to overload. A one-stage arrangement thus: 2 @ 9×8-ft. ball mills → 2 rakes each of the quadruplex classifier, sands to mills → Cascade flotation machines, concentrate finished → 2 bowl classifiers in parallel, overflow finished, sands to mills, raised the tonnage to 1,000 tons per mill per day to 90% <200-m. The change had the further result of decreasing steel consumption, which, in the secondary mills, had been double that in the primary owing to absence of primary slime, and of more than doubling the life of the pumps elevating mill discharge, the same explanation holding. At NEW CORNELIA (*153 A 333*) a two-stage circuit similar to item *4*, Fig. 72, except that a part of primary-classifier sand was cut back to the primary mill, was changed to the circuit, item *2*, after prolonged testing had indicated an increase in section capacity of 4.2% and a decrease in power consumption per ton of 3.5% with the single-stage operation.

Justification for a second grinding stage usually lies in improved metallurgy due to finer grinding; the economic advantages of this must exceed the increased operating cost. Justification for a tertiary circuit is found in the necessity for an excessively fine grind, the presence of a high resistance to fine reduction, or possibly to a demand for increased capacity that can be more cheaply or effectively satisfied thus than by increase in secondary units.

Canadian practice is a valuable indicator of present-day milling opinion because more new mills have been built there over the past 15 years than in any other part of the world, and practice has not been hampered by existing installations. Analysis of that practice by Hanson (*140 #6 J 39*) follows. In the PORCUPINE district, where metallurgical demands are satisfied by a grind to 65 to 80% <200-m., single-stage grinding predominates. The ADVANTAGES are: less floor-space required, less attendance, larger units with corresponding economy in power and steel consumption. DOME is an exception on account of the coarse gold present, which demands an open-circuit primary mill with removal of coarse gold on blanket tables ahead of the secondary circuit. Feed to the primary must be kept down on account of lack of a circuit guard. At the other mills of the district the gold is finer and is taken care of generally by roughing on blankets, shaking tables, unit jigs or flotation cells in the grinding circuit. In the KIRKLAND LAKE district metallurgical requirements call for grinding to 200 *mog*. Here two stages are used in all plants and three in some. Feeds to the grinding circuit are 3/8- or 1/4-in.

limiting. Relatively short mills in closed circuit with standard rake or spiral classifiers are usual. Secondary mills are tubes in closed circuit with bowl classifiers, mill feed being the deslimed product of the primary circuit.

Concentrating practice in the early 1930's in copper and lead-zinc mills, as sampled by the Bureau of Mines (*IC 6792*) showed 9 @ one-stage, 15 @ 2-stage and 1 @ 3-stage installations out of 25 reported. Of the one-stage operations, two were rod and 7 were ball mills. Of the two-stage operations, the primary stage was rod mill in 4 and ball mill in 11; the secondary stage was rod in one, ball mill in 14. During the 1930's, in so far as changes in the larger mills were concerned, the trend was toward multistage.

Balancing stages so that the energy and capacity available in each stage are utilized effectively is the desideratum—and bugbear—in stage grinding. It is difficult, and rarely practical, to determine the conditions for even approximate balance in advance of installation, for the reasons that (*a*) the optimum diameter and diameter-length ratios of primary mills are different from those for secondaries unless the feed to the primary is relatively fine ($<3/_{16}$-in.) and the final *mog* relatively coarse (48); (*b*) the grindabilities of the primary and secondary feeds are usually different, and vary with the size of the primary product; and (*c*) the optimum capacity of the secondary circuit is necessarily a whole-number multiple of a relatively large fraction of the primary-circuit capacity. As a result, the installation is usually made on the basis of a guess, more or less shrewd according to the experience and ability of the designer, and operation then becomes a continual fight to get and keep in balance. Increase in power per unit of reduction following an increase in stages is *prima facie* evidence of initial lack of balance, and such an increase without a correlative change in character of ore during stage operation indicates a decrease in degree of balance.

At Wright-Hargreaves (*140 #4 J 37*), after long experimentation on a hard, siliceous ore, the following conclusions were reached as to the proper principle to govern balancing: (1) Production of <200-m. (the desired finishing *mog*) is done most efficiently in tube mills charged with small balls and fed with a granular product as fine as possible. (2) Production of such granular secondary feed is best attained by getting finished material out of the primary circuit as quickly as possible. (3) This may be done by reducing the time per pass in the primary mill either by (*a*) a high new-feed rate, or (*b*) a high circulating load (attained with constant feed rate by decreasing the size of primary classifier overflow), or (*c*) by maintaining a steep pulp gradient through the primary mill.

At Hollinger advance provision was made for combating both difficulties by providing for variable speed of one out of four secondary mills (*134 A 331*). Change in weight of tumbling load in one of the circuits is an analogous remedy. Change in ball size in the secondaries is a common expedient. Hour-to-hour operating adjustment is effected by control of the primary-classifier overflow or, in aggravated unbalance, by change of new-feed rate. Dorr and Marriott (*87 A 112*) warn against changes from one-stage to multistage grinding in which the old single-stage mill is made the primary with no change except, perhaps, an increase in ball size, and without increase in, or even with elimination of facilities for classification.

Grinding flowsheets differ not only in number of stages but in the kind and placing of circuit guards. Essential differentiations in the latter respect are whether new feed is deslimed or otherwise scalped before entering the primary mill, and whether desliming or other unloading classifiers precede the subsequent circuits. Fig. 72 presents typical circuits.

Circuit *1* is substantially a scrubbing circuit, used, for example, with a light rod load in preparing pebble-phosphate feed, P_2, for table flotation, after discard of slime P_1. Circuit *2* is a typical one-stage flow, taking whole feed. Circuit *3* is substantially the same, except that the mill feed is scalped by the classifier. Flow *3a* is a variant used at Morris Kirkland for one-stage grinding from $3/_8$-in. to 80% <325-m. Flow *4* comprises an open-circuit primary mill, a separate scalping classifier, of rake type, and a closed secondary circuit, with the classifier overflows joined. This is typical of flotation circuits using primary rod mills in what is substantially secondary crushing. Flow *5* is typical 2-stage grinding for flotation, with whole feed to the primary mill and the burden of final separation on the secondary classifiers. It works satisfactorily, if the ore is reasonably clean and the *mog* not less than 65. Flow *6* is a variant of *5* used when the feed contains much primary slime which makes classifier operation difficult but is not harmful in flotation. Such removal is an aid to selective grinding of sulphide in the secondary circuit. Dyrenforth and McArthur (*87 A 149*) credit preliminary desliming at Miami with an increase of 18% in the amounts of <48-m. and <200-m. produced per primary mill, but inspection of the supporting data shows that the change in feed size was accompanied by a marked increase in tonnage of new feed and a coarser primary-classifier overflow, both of which would work to the same end. These authors also credit preliminary desliming at Nevada Consolidated (McGill) with increases of 16% in <48-m. and 42% in <200-m., 28% saving in the power consumed per ton of new feed, and 30% saving in the power consumption per ton of <200-m. produced. At Chino (Anable, *126 J 990*) the percentage of >100-m. in the primary-circuit product was decreased 5% by preliminary desliming, which is equivalent to 5 to 10% increase in capacity to 100 *mog*. On the other hand, Bates (*73 A 313*) reported that at Utah complete desliming of primary-mill feed reduced capacity; at Roan Antelope (*ibid.*) it was noted that the presence of primary slime in the primary mill increased adherence of pulp to the grinding media and resulted in better performance; and Dorr and Anable (*112 A 168*) warn that removal of primary slime may make control of classification difficult in succeeding circuits. At Consolidated Mining & Smelting Co. (*87 A 108*)

passage of primary slime through the ball mills was found to better flotation results, probably by removal of oxide coatings from the sulphides. Parsons (*60 CMJ 693*), bearing in mind the danger of overgrinding flotation feeds, recommends short ball mills and multiple classifiers therefor, and long tube mills and ample classifier-overflow capacity for gold ores.

Flow *7* is the variant of *5* applicable when the *mog* is finer than 65. Flow *8* is another variant of *5* used when it is desirable to float primary slime separately, but some mill action on the sulphides therein is desirable. It may also be used simply to unload the secondary circuit, *e.g.*, at CANANEA (*87 A 112*) such a bowl removed 40% of the section tonnage; overflow was recombined with the product of the secondary circuit for flotation. The intermediate classifier also tends to steady operation in the following circuit. At NEVADA CONSOLIDATED (*87 A 125*) it was found that the intermediate desliming classifier increased capacity but harmed metallurgy.

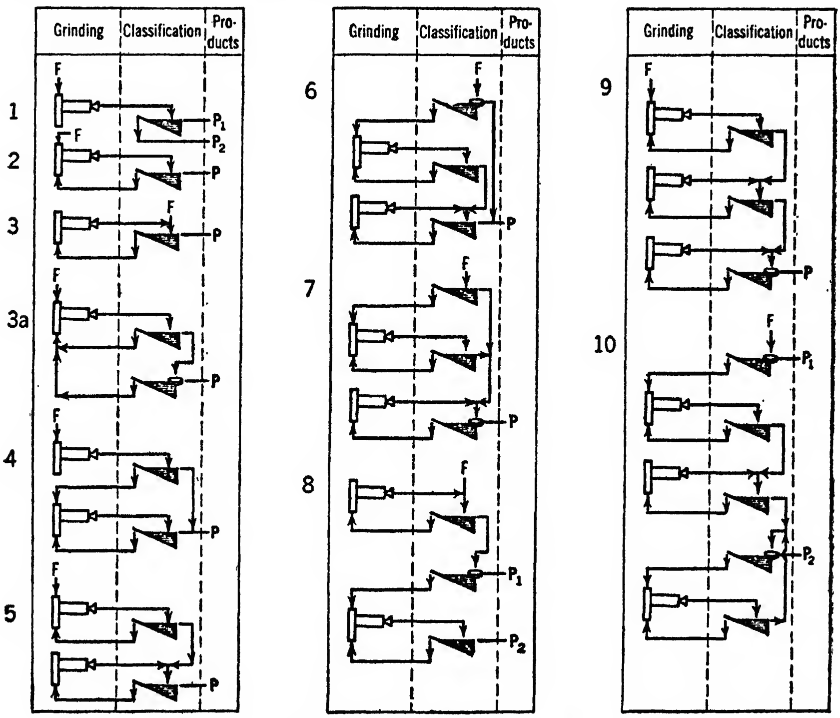

FIG. 72. Typical grinding circuits.

Flow *9* is a typical 3-stage set-up for a final *mog* less than 100. Flow *10* provides for very fine grinding with preliminary removal of primary slime when its presence is harmful in the later classifiers, and for relief of sand load on the final bowl.

The disadvantage of flowsheets comprising only one primary mill is that the entire section capacity is lost whenever the primary circuit is shut down; the loss in machine time is the greater, the more secondaries are installed per primary.

Reagents in grinding circuits may or may not affect the performance of the circuit appreciably. COLLECTORS tend to decrease overgrinding by floating off sulphides by skin flotation, but coarse middling and tramp coarse mineral may be carried over also. Such flotation in the classifier is accentuated, if there is any FROTHING AGENT present in the circuit. LIME may either aid or hinder. McClelland (*Bul 342 CIMM 407*) states that addition of 1.5 lb. per ton to a primary rod-mill circuit increased capacity 15 to 20% since the resulting flocculation decreased the effective sp. gr. and viscosity in the classifier, permitting quicker and cleaner settlement of sands, and the decreased viscosity of the pulp in the mill increased the grind per pass. On the other hand such flocculation with high-sulphide ores has resulted in marked overgrinding in a number of mills because of the substantial impossibility of lifting flotable sulphide into classifier overflow.

At BEATTIE (*112 A 690*) circuit efficiency improves with increase in alkalinity up to 0.004% free Na_2CO_3; above this classifier efficiency falls rapidly. At the same plant alkalinity in the concentrate-

regrind circuit destroys classification completely. At MORENCI (*PC*) there is considerable clay in the ore; this tends to flocculate and carry oversize into classifier overflow even when overflow density is dropped to 16% solids. The ore is sensitive to lime; a slight drop in alkalinity below normal causes coarse sulphide to overflow, too much lime causes flocks to form and carry over spongy siliceous oversize.

Frothing in grinding circuits in cyanide plants is usually caused by soda greases. It tends to carry coarse metalliferous and calciferous rock out of the grinding circuit (and hurry it through the cyanide circuit). The remedy is drip pans at the proper places and cleanliness throughout the mill.

13. SIZES OF FEED AND PRODUCT

Size of feed to primary grinding circuits ranges from about 10-m. limiting to as large as 3-in.; feeds coarser than 1 1/2-in. are, however, unusual, and are found, in general, only in plants of small capacity where the most efficient operating balance between crushing and grinding is undesirable from a first-cost standpoint.

Finished size is almost universally taken out of the feed to mills other than primaries, but practice differs with respect to the latter. Introduction of new-feed undersize to the mill has the disadvantage that some overgrinding necessarily occurs. On the other hand, the percentage of undersize in primary feeds is usually small, and the quantity relative to the undersize returned with circuits sands tends to be negligible. Further, some operators assert improvement in pulp consistency due to primary slimes in the mill. (See Art. 12.)

For sizes fed to specific types of mills see Arts. 7 to 11. In general, feed sizes may be larger the softer the rock. It is worthy of note, as regards smoothness of operation, that size segregation in mill bins is less the finer the feed.

Size of product is the most talked-about subject around a grinding plant and the one of which the least, perhaps, is known. For discussion of methods of size measurement see Sec. 19, Art. 18. For screen analyses and screen-size distributions characteristic of products from specific types of mills see Arts. 7 to 11. The essential showings of these curves are summarized in Table 43.

Table 43. Size characteristics of products of different tumbling mills

Mill	Open Circuit						Closed Circuit					
	80% size, % of limiting screen			Aperture passing 50%, % of limiting			80% size, % of limiting screen			Aperture passing 50%, % of limiting		
	Ore			Ore			Ore			Ore		
	Soft	Aver.	Hard	Soft	Aver.	Hard	Soft	Aver.	Hard	Soft	Aver.	Hard

Grate ball mill	......	......	......	......	......	......	25	34	51	8	11	25
Conical ball mill	17	24	28	3	8	12	23	27	37	7	9	17
Tube mill	......	......	......	......	......	......	......	......	50	......	......	25

Fortunately, in ore-treatment mills the object of grinding is to liberate or expose the valuable mineral. Hence the effectiveness of grinding, all other things being equal, can be measured by the metallurgical results. Fortunately again, experience over the years has shown that for a given ore, with given grinding and accessory machines, a definite correlation exists between metallurgical results and certain screen-size characteristics of the ground product. Hence these size characteristics are chosen for operating control of grinding.

Size characteristics normally used for operating control, stated in order of increasing difficulty of ascertainment and interpretation are: (1) *mog*, (2) percentage coarser than the *mog*, (3) percentage coarser than the peak of the distribution curve, (4) percentage finer than the finest sizing used. Thus the operator speaks of a 10-m. or 65-m. grind, implying, properly, not more than a fraction of 1% on the screen named; or of some 2 or 3 or 4% on the *mog*, implying appreciable differences in metallurgy and capacity between the different percentages; or of 15 or 25 or 50% retained on the screen corresponding to the peak of the distribution curve, with an implication similar to the preceding; or to 30 or 60 or 90% <200- or <325-m. of <10-μ, again with the same implication.

The most elaborate published correlation of size of ground product with metallurgical performance is, perhaps, the LAKE SHORE work (*LS*), summarized in Fig. 73.

The relative utilities of the size controls above mentioned depend upon the mineralogical characteristics of the ore and upon the method of recovery employed. At LAKE SHORE the gold is very finely disseminated and is recovered by all-slime cyanidation. Hence, since the extraction process was geared mechanically to a constant efficiency over the range of sizes covered by the tests, metallurgical results varied directly as the degree of exposure of gold. This, in turn, varied directly with the size of particle in the ground product. But see also Fig. 74.

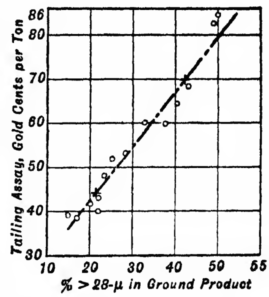

FIG. 73. Correlation between tailing assay and grind at LAKE SHORE.

Constant percentage of intermediate sizes in a ground product was reported by the Lake Shore Staff (*LS*) and confirmed by Dzingheuzian (*34*[2] *Bul CIMM 362*). At LAKE SHORE the sum of the >28-μ and <10-μ percentages in the ground product was constant; at SISCOE it was the sum of the >65-m. and <200-m. percentages. This relationship is characteristic of the behavior on comminution of a heterogeneous material composed of hard and softer minerals, when a substantial quantity of the former is freed as individual grains at the coarse end of the range of grindings investigated. If, now, the range of grindings is not too great, with increasingly finer grinds the softer material is ground preferentially, and that fraction of the early released hard material that is further ground by prolonging the operation is substantially balanced by the amount of hard fraction freed from coarse homogeneous grains. Hence the location of the distribution line through the constant intermediate hard fraction remains constant, as does, of course, its slope, while the slope of the fine part of the line flattens progressively as greater and greater amounts of soft material are transferred to this range from the coarse end.

When, as is the case at LAKE SHORE and SISCOE, the bulk of the values is in the softer sulphides, the transfer of material from one end to the other of this constant zone measures the utility of the grind.

Overgrinding. When the values in an ore free at relatively coarse sizes and/or the recovery process becomes progressively more inefficient as particle size becomes finer, the relation between tailing loss and percentage passing some key mesh is no longer a straight line throughout the range of grind possible in normal operation, but will show a minimum which represents optimum metallurgy (and usually optimum profit). Fig. 74 is typical; more detail is shown in Sec. 12, Figs. 55, 56. But see Fig. 73. A grind which is finer than that corresponding to the optimum is characterized as OVERGRINDING.

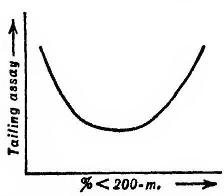

FIG. 74. Grind *vs.* metallurgy in concentration.

Overgrinding occurs at relatively coarse sizes with gravity and magnetic concentration; from the process standpoint alone, 100-*mog* is probably close to the danger point for sulphide flotation, but here the optimum is also so closely bound up with the size distribution of the valuable mineral as to make determination of the economic optimum a necessity for each ore and mill. In any event, allowable tailing losses, measured by weight, are so much higher than in cyanidation that a less precise size control is permissible. Hence the percentage passing 200- or 100- or even 65-m. is a wholly sufficient operating control.

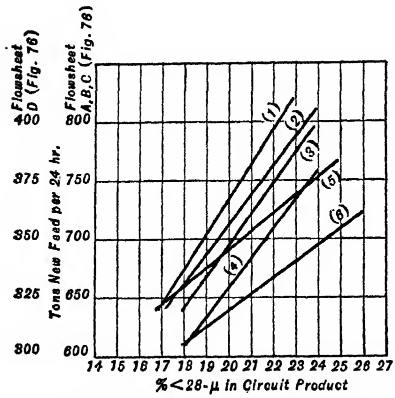
Operating factors controlling size of product are discussed in detail in the articles dealing with specific elements of operation. Fundamentally the size of product depends on the size of feed, its resistance to comminution, the intensity of the grinding forces available, the efficiency of their application, and the duration of their action.

Size of feed affects size of product to the extent that the forces available are limited. If a mill is of small diameter, the tumbling bodies are light in weight or small in number, and/or the speed is such that their momentum is small, coarse feed will cause a coarse product unless the duration of grind is excessive. If, on the other hand, the converse of the above postulated operating conditions prevails, so that adequate force is available for breaking large lumps readily, then considerable variation in maximum feed size within accepted maximum feed-size limits (1/2-in. to 1 1/2-in.) will cause but small variation in size of product, since this is then controllable to a large extent through adjustment of feed rate and/or the circuit guard (Art. 12).

Grindability is the greatest single factor in determining size of product when all other conditions remain constant. At plants where there is marked difference in grindability between ores from different parts of the mine while the metallurgical treatment demands a constant *mog*, feed rate (duration of grind) must be varied to compensate for ore changes, or sufficient suitable storage must be provided to permit efficient blending to a mixture of constant grindability. See also Art. 14.

Fahrenwald (*140 #2 J 73*) states that the more resistant an ore is to comminution the coarser the average size of the product ground to a given *mog*.

Intensity of grinding forces depends upon diameter of mill, conformation of the inner surface (Art. 5), size and shape of tumbling bodies and the amount thereof (Art. 6), and mill speed (Art. 2). Since fineness of product varies as the amount of energy expended,



Legend, Fig. 75.

5. Flowsheets A and C, Fig. 76, all mills high-discharge.
6. Flowsheets B and D, Fig. 76, all mills high-discharge.

The operations summarized in Fig. 75 comprised the entire unit of four grinding sections as shown in Fig. 76, and extended over a period of several years. Owing to variations in grinding capacity with liner wear (see Art. 5), adjustment to a common base was necessary for construction of Fig. 75. This adjustment was made by equation $C \propto D^{2.6}$ (see Art. 14), to bring all capacities to a basis of 2-in. liner thickness.

FIG. 75. Comparative capacities of mills with high and low discharge at LAKE SHORE.

all other things being equal, and force is one component of such work, it follows that product size will vary with changes in any one of the three elements mentioned. The extent and nature of the dependence are discussed in detail in the reference articles.

Efficiency of force application depends upon the size of feed, the characteristics of the tumbling bodies, the distribution of the material in the grinding zone, and the form in

FIG. 76. Flowsheets for Fig. 75.

which it is presented to the grinding surfaces. The coarser the largest feed particles, the less efficient the application of force both to them and to the finer particles (Arts. 2, 3). Proper rationing of the tumbling charge to the feed size is essential to efficient force application (Art. 6). The material to be ground should be present at all times at the contacting surfaces of all tumbling bodies, in such quantities as to utilize fully the forces available.

This means practically that the amount of interstitial material should be limited to such an extent that the interparticle pressures of the tumbling media are not dissipated by compacting of rock particles, while, on the other hand, the amount and consistency should be such as to maintain a layer at all times between approaching surfaces of tumbling media. Departures from any of the optima of efficiency results in a coarser product. Quantity of interstitial material depends upon height of discharge (Art. 3) and upon total feed rate (Arts. 12, 14). For the effects and control of pulp consistency see Art. 16.

Duration of action and size of product vary inversely. The character of the variation under a number of different conditions on one ore is shown in Fig. 75. The limits to the relationship are not known. It is to be expected to break down if the natural grain size is below the *mog*, particularly if the natural grains are tough. It also should fail if the tumbling load is improperly rationed to the feed, or if any part of the circuit becomes seriously underloaded or overloaded throughout the range of tonnage variation. See also Art. 14.

Cost of increasing fineness of grind comprises the overhead involved in reduction of capacity, the additional power, and additional steel consumption. At UTAH with an 8~10-m. feed, a reduction in *mog* from 48 to 100 cost 2¢ per ton, or 25% of the cost of the coarser grind. The cost of a corresponding proportionate decrease in *mog* from 100 to 200 would be considerably greater. Both the relative and absolute increases would be larger at plants treating lower tonnages. See also Art. 20.

14. CAPACITY

Definition. The capacity of a grinding section in an ore-treatment plant is, properly, the amount of material that it reduces to a satisfactory liberating size per unit of time. If the section comprises successive grinding units, only the last of these is charged with finishing liberation. Each of the earlier mills fulfills its function by delivering to the subsequent unit a product of some prescribed limiting size based upon balance between the stages (Art. 12). Liberation in the final mill will also have been correlated with some particular *mog* (Art. 13). Hence as a practical matter, the capacity of each unit in the grinding circuit (grinding unit with or without a guard) is normally stated as the amount of material fed per unit of time when the circuit is discharging at the desired limiting size. CAPACITY involves always, therefore, the elements of quantity, time, and limiting size of product.

Controlling factors are both structural and operating. The STRUCTURAL FACTORS are the shape and dimensions of the barrel, the liner, and the shape, dimensions, quantity, and material of the tumbling load. The OPERATING FACTORS are the lithological character of the feed, its size and size distribution, and its consistency as determined by the quantity of water with which it is admixed; the size of product, the mill speed, the apparatus in circuit, and, last but not least, the operator.

Power and capacity. The most fundamental approach to the question of capacity is, probably, to look upon the tumbling mill as a mechanism in which kinetic energy in a form capable of doing crushing work is made available to be utilized when feed pulp is moved across the surfaces of the tumbling bodies. In such a view a fundamental measure of performance is the tonnage of product having the desired characteristics which is turned out per unit weight of tumbling load per unit of time, *i.e.*, $C =$ tons of finished product per hr. per ton of tumbling load. Mill capacity T then equals CW, where W is total weight of tumbling load in tons. This approach has the advantage that it sets up as the goal the endeavor to so design and operate as to make a given shell draw the maximum possible power consonant with efficient transformation of the resultant energy of the tumbling load into crushing work on the rock passing through the shell.

The tumbling mill differs from all other crushing apparatus in that it draws nearly maximum power when doing no useful work, *i.e.*, when a dry tumbling charge without rock is being rotated. The procedure of the operator seeking maximum capacity from his mill should be to determine the charge weight and speed that result in maximum power draft, and then to find the feed conditions that produce the desired grind with minimum recession from full power draft. The limiting factor in this search is steel wear. Optimum conditions are those in which the tonnage of desired product per dollar of combined cost of power and steel is a maximum.

Capacity figures presented in the various performance tables in Arts. 7 to 11 are by no means all optima. The averages are, in general, safe for design purposes. Good operation, when not subject to limitations with respect to tonnage of ore available, or to special limitations imposed by metallurgical requirements, should always yield results well above the averages for ore of similar resistance characteristics.

The nature of the effects on capacity of the various structural and operating factors above mentioned are discussed under the various item headings, *q.v.*

[a] See Sec. 19, Art. 11.

Grindability of the ore is the most potent factor in determining mill capacity. It has a number of facets, hardness, toughness, natural grain sizes and shapes, mineral ratios, and *mog* being the most important. Methods of testing are given in Sec. 19, Art. 11.

Hardness determines the ease with which a particle is nipped by a given tumbling medium; the harder the particle the less likely it is to slide away from the crushing zone. Thus quartz grinds to fine sizes much more readily than mica or graphite.

Toughness is difficult to define other than by example. From the grinding standpoint native copper is much tougher than quartz, quartz than feldspars, the latter than calcite or dolomite, and these than cerussite. The question is not wholly one of cleavage, since mica is tougher at right angles to the cleavage than quartz, as are also many of the basic silicates, if the measure be taken as resistance to grinding. Table 48 indicates, if the three hydrocarbons are excluded, that hardness and cleavage both correlate definitely with grinding resistance.

Natural grain sizes are important because, in general, ores composed largely of rock-forming minerals break more easily along grain boundaries than across the grains. This is particularly true of sedimentary materials but is also noticeably true of igneous and metamorphic rocks. Minerals with strong cleavages and the sulphides in general usually break across the grains. When boundary breaking occurs and the individual grains are tough, grindability decreases greatly at the finer *mogs*.

Thus at Nacozari (C. F. Thompson, *PC*) a 6×12-ft. primary rod mill ground 11.5 t.p.h. from <1 1/2-in. to 48 *mog* while the same mill in secondary service on the same ore, regrinding sand from the primary classifier, could grind only 9.4 t.p.h. to the same *mog*.

Mineral ratios determine the proportions of the different kinds of grains and thereby the amount of easy through-grain breakage above natural-grain sizes and the amounts of resistant grains to be reduced after gangue-grain release. The effect on International Nickel ore (*58 CMJ 665*) is shown in Table 49.

Mog determines, for any ore, the amount of grinding that must be done on tough released grains. Since natural-grain sizes range from 10- to 65-m. for the majority of gangues—even when these are largely one mineral—grindability for a given ore will vary considerably according to whether the *mog* is below the natural grain size and how much below.

Grindability ratings made by a number of different investigators using different methods of determination are given in Tables 44 to 47.

Mortensen (*131 J 225*), on the basis of laboratory ball-mill tests, lists the following relative grindabilities: Quartz, 1; miscellaneous pyritic ores, 2.5 to 4; gabbro, 2.7; fine-grained granite, 3; magnetic iron ores, 3 to 4; soapstone, 8. Gow *et al.* (*loc. cit.*) report chert three times as difficult to grind as dolomite (moderately hard), and Bond and Maxson (*134 A 296*) report this same chert the most difficult to grind of all the ores listed in Table 44. Coghill and deVaney (*CEG*) state that this chert requires 28 hp-hr. per ton to grind from 6-m. to flotation size. Kuzell and Barker (*IC 6343*) state that the grind resistance of the southwestern copper ores, in increasing order, is: UNITED VERDE massive sulphide, UNITED VERDE schist, COPPER QUEEN, INSPIRATION, NEVADA CONSOLIDATED (McGill), MIAMI, MOCTEZUMA, NEW CORNELIA. Traylor Eng. & Mfg. Co. rates comparative grinding resistances of various well-known ores as follows: CALUMET & HECLA, 1.33 (most resistant); PORTLAND, 1.00; NEW CORNELIA, 0.92; GOLDFIELD CONSOLIDATED, 0.79; MIAMI, 0.70; HOMESTAKE, 0.63; MORENCI, 0.51; COPPER QUEEN, 0.46; UTAH, 0.38; RAY, 0.37. ROAN ANTELOPE lies between MIAMI and COPPER QUEEN (C. F. Thompson, *PC*).

Table 46. Data on crushing resistance by scleroscopic determination (*After Dean et al., RI 3223*)

Mineral	Specific gravity	Hardness	Weight of material crushed per unit of work, grams *a*	Scleroscope data for mineral section, 1.2 in. thick

a A 35-min. grind of <10-m. Lake Shore feed in a 12-in. laboratory rod mill yields a ground product of the same size and size distribution as the 3-stage plant circuit.

Warning. Grindability data must be used with discrimination and caution. Thus Table 47 indicates relatively little difference between HOLLINGER and SYLVANITE conglomerate ores in grinding from 10-m. to 200 *mog* (35-min. grind) although considerable difference is shown on the 8-min. grind. Rodgers (*40 CIMM 329*) compares operating data in Table 50. This points up the practice of Bond and Maxson (*134 A 296*) to make grindability tests to the *mog* to which the mill is to operate.

Size of feed has an important effect on grindability when the *mog* is very fine. Thus at LAKE SHORE (*LS*) sands sized substantially to the micron ranges shown in Table 51 were ground in a laboratory batch mill for 20 min. at best pulp densities under otherwise constant conditions. The increasing resistance to further reduction with decrease in feed size is striking.

Capacity formula. It follows from the fact that net power draft varies as mill diameter raised to the 2.6 power (Art. 15) that the capacities of different mills under analogous conditions would follow the same variation. This has been confirmed by Gow *et al.*, Fahrenwald, and the staffs at HOLLINGER and at LAKE SHORE. Mine & Smelter Supply Co. (*PC*) interpolate on the assumption that the variation is as D^3 in setting up their catalogue figures for mill sizes for which actual performances are not available. Bond (Allis-Chalmers Co., *PC*) states that commercial grinding results tabulated by him show that capacity varies as $D^{2.2}$ when the mills are operated at speeds recommended by Allis-Chalmers (Art. 2), while the variation is as $D^{2.6}$ for mills operating at 80% of critical.

Table 48. Grindability of minerals *vs.* hardness and cleavage (*Based on data by Coe and Coghill, RI 3704*)

Material	Relative resistance to grinding *a*	Cleavage or fracture	Hardness, Mohs

Change of mill capacity. Reduction is effected by reducing power draft. The usual methods are by reducing mill diameter by inserting wooden backing between shell and liner (Fig. 16); reducing length by inserting a false discharge head or grate (*87 A 75*); reducing ball load without other change (30% charge is about the limit, *112 A 45*); change to a lighter medium, *e.g.*, pebbles; or reducing speed. Which of these is the most economical is not established; it is probable that over a long period the first is, provided the reduced diameter is sufficient to reduce the coarsest feed particles. Increase is usually possible by increasing charge or speed or both, especially if the mill has been bought on a noncompetitive basis. If the mill is of overflow type, it can always be changed to grate type to hold a larger tumbling load, although a larger motor will usually be necessary. Increase in classifier capacity to tolerate larger circulating load also is effective (Art. 12). Liners with more lifting effect increase capacity in primary mills: use of thinner liners is effective in both primary and secondary mills, but

Table 50. Comparison of grinding at Hollinger and Sylvanite (*After Rodgers*)

% of size in feed	89.3	93.4	84.7	87.0	76.0
% of size remaining	18.1	32.8	51.2	60.4	76.4

will increase liner cost on account of increased discard percentage. Some gain can usually be obtained by simple increase in the alertness and skill of the operator.

Flow capacity. In buying a mill, its capacity as a conveyor must always be investigated, particularly if high circulating loads and/or coarse feeds are contemplated. Feeder must be of proved ample capacity, and preferably should be capable of building up some head against the feed trunnion. In a grate mill the feeder must be capable of passing the largest renewal ball. The feed trunnion should be of such diameter as to receive a trunnion liner with a definite flare toward the mill shell, or to permit of spiral rifling at least $^5/_8$ the depth of the largest feed particle. Grate openings should be as large as is consistent with holding back the smallest ball desired in the charge, and the total area of working opening (30 to 40%, usually, of the total area of opening) should be at least twice the working cross-section of the feed trunnion. Since the latter figure is difficult to determine, it is usual to make the working total opening of the grate at least equal to the cross-sectional area of the feed trunnion. The capacity of the discharge elevator in a grate mill must be sufficient to keep the pulp level between the grate and the discharge head down to the periphery of the perforated portion of the grate diaphragm. In overflow mills the discharge trunnion should be large enough to allow for a larger drop than it is contemplated to use. Excess drop can then be taken up by a suitable annulus or spout (*e.g.*, Fig. 44), which may be changed cheaply as the occasion demands.

Purchase of a mill. Large companies usually have past records available and/or opportunity for testing that make selection of the right mill a virtual certainty. The purchaser for a small mill, however, will do well to consult with at least two reputable manufacturers, submit representative samples of the material to be ground, and check estimates both against each other and against published and otherwise available data. His danger will not, in general, be under-capacity, but rather the reverse, which entails a continuing charge because of inefficient use of power; the mill recommended will almost certainly do the job, but not in the most efficient fashion. However, if the operation is successful, his first and early demand will be for increased capacity, and this his seller will be able to pull out of a hat.

15. POWER

Definitions. Net power draft of a tumbling mill is the rate at which work must be done on the tumbling load by the shell in order to maintain the center of gravity of the load in a position of kinetic equilibrium out of the vertical plane through the axis of rotation of the shell. TOTAL POWER is net power plus friction and transmission losses. Net power is not capable of analytic determination because of present ignorance of the internal dynamics of the tumbling load.

Theoretical power draft. Gow *et al.* (*112 A 27*) indicate the elements of an analytic attack, pointing out that power P varies as the ball load, which in turn varies as the square of the radius r for a given shell length; that power likewise varies as the torque arm, which varies as the radius times a function of the angular displacement of the center of gravity of the load; and that it varies as the critical speed, which is an inverse function of the square root of the radius; whence it follows that $P \propto \frac{r^3}{\sqrt{r}} \propto r^{2.5}$.

Experimental determinations of power draft. Gow *et al.* (*87 A 51*) and Fahrenwald and Lee (*A TP 376*) have shown experimentally that for small laboratory mills working under similar conditions power varies nearly as $D^{2.6}$, where D = internal diameter of mill. Gow *et al.* (*112 A 24*) showed that this relationship held as between a 2×2-ft. laboratory mill and a 6×4-ft. commercial mill. Finally the Hollinger Mill Staff (*HS*) and the Lake Shore Staff (*LS*) have demonstrated the applicability of the same variation to large ball and tube mills operating in the respective plants. Hence, if the net power draft of a mill of one diameter operating under given conditions on a given ore is known, the corresponding figure for any other mill of the same length but of different diameter, operating under the same relative conditions, can be estimated. Differences of length may be taken care of by the equation

$$\frac{P_1}{P_2} = \frac{D_1^{2.6}L_1}{D_2^{2.6}L_2}$$

where P, D, and L are power, diameter and length of mills 1 and 2 respectively. Gow *et al.* (*ibid.*) showed that if the net power consumed by a 2×2-ft. laboratory mill with which they worked were represented by p, the net power for any large mill operating under analogous conditions was closely approximated by the equation

$$P = \left[\left(\frac{L}{2} - 1\right)K + 1\right]\left(\frac{D}{2}\right)^{2.5} p$$

where K = 0.9 for a mill length less than 5 ft. and 0.85 for length greater than 5 ft. P is horsepower, D and L are stated in ft., and p = 2.2.

Hancock (*112 A 77*) proposes the formula $HP_N = 0.00078C^3L\delta n$ for net horsepower where C = length in ft. of the chord defined by the surface of the mill charge (tumbling media plus pulp) at rest, δ = mean specific gravity of charge, L = inside length in ft. and n = r.p.m.

Friction loss was determined by Gow and Guggenheim (*133 J 632*) by packing the ball load of a 6×4-ft. mill in balance around the mill axis. They found that the power-speed curve was a straight line passing through the origin, and that for 80% of critical speed the loss was 11 hp. as against an operating consumption of 87 hp. Hence the percentage loss was 13. Motor efficiency in the particular case was 90%. Thus net power was 0.9 × 0.87 = 77% of power input. They assert that dead load, being primarily the result of friction, is proportional to speed. Martin (*25 Cer S 63*) says that speed varies as $n^{1.5}$ where $n =$ r.p.m., and tests on laboratory mills by Coghill *et al.* (*112 A 82*) indicate that friction increases faster than speed. Coghill (*87 A 77*) asserted the belief that net power in some small old-type ball mills is as low as 50% of input. Stroup (*87 A 77*) asserted that similar dead-load tests which he had made by symmetrical packing of liners weighing the same as the ball load showed not over 5 to 6% dead-load loss.

Coghill *et al.* (*112 A 80*) applied the formulas of Gow *et al.* (*loc. cit.*) to the dead-weight figures from the catalogues of several manufacturers and concluded that friction losses allowed for would range from 11 for an 8×5-ft. mill to 40% with a 3×5-ft. mill. Maxson (*112 A 85*) pointed out that in order to minimize dead-load losses the ratio of dead load (shell, liner, gear, and feeder) to live load should be a minimum. Roller bearings on countershaft and trunnions have not saved power as against ordinary bearings of good design, but have some advantages in lubrication and care (*87 A 76*).

Unbalance of the mill causes power peaks that increase total power; Gow *et al.* (*112 A 27*) report a mill in which a 20% jump in power was indicated by a meter each time the single-scoop feeder dug; at another mill there was a perceptible jump as the belt splice slapped the motor pulley; rod-mill power consumption is less smooth than that of a ball mill; a single manhole in the shell of a small mill produces perceptible unbalance.

Starting usually causes a short, high peak but Gow *et al.* (*ibid.*) assert that if the load is not packed, and if provision is made for slow acceleration, operating speed may be reached without exceeding maximum operating power (see also Sec. 20, Art. 7).

Controlling variables. The net power draft of a tumbling mill is due to the braking action of the load applied to the interior of the shell, not to the grinding work that the mill is doing at any instant except in so far as the conditions under which such work is being done affect the braking power of the load. Thus net power is affected by various operating conditions. It increases with tumbling charge up to 50% of mill volume and then decreases (Fig. 77), except that with interstitial loading of relatively large volume the maximum point in power draft may be reached before the actual load of medium reaches the centerline. Effects of variations in interstitial filling are shown in Table 52. With a given tumbling load power is a maximum with an interstitial load that just fills the interstices (*112 A 27*). It is higher with coarse sand than with fine (Table 52). It is higher for low discharge than for high (Table 5). In a grate mill, a drop in power draft indicates clogging of grates. Power increases with decrease in pulp density (Table 52). It increases with the lifting effect of the liner. It increases with liner wear (increase in mill diameter), provided the surface of the liner does not change to the extent of increasing slip materially (Table 53). It decreases slightly with increase in feed rate (Table 52). It increases with speed up to the point that cataracting begins, then drops (*112 A 27*). It is higher with hard ore than with soft, and higher with ores of high specific gravity.

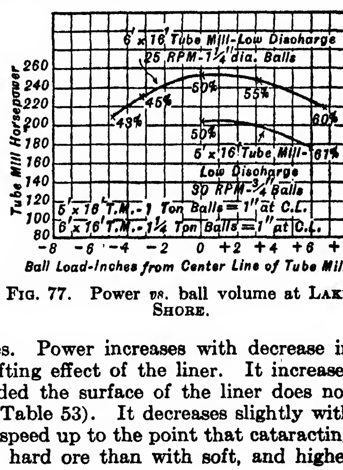

FIG. 77. Power *vs.* ball volume at LAKE SHORE.

Shape of tumbling bodies affects net power consumption per ton of tumbling media both by its effect on the length of the lever arm and on the internal friction of the load. Thus rods, which weigh more per unit volume of load than balls, can be loaded into a mill of smaller diameter than balls for the same weight of tumbling charge per foot of mill loaded to a given percentage of mill volume, and therefore require less net power per ton for tumbling. Shapes that tend to maintain large contact area per unit weight of charge will, if slippage against the breast of the mill is prevented by suitable liners, tend to ride higher in the mill than otherwise and thus increase power consumption. On the other hand, shapes which key and tangle consume less energy in internal friction in the mass than those with which relative motion is high, and net power consumption is relatively low despite possible high lift on the breast of the mill.

Shape of lining has marked effect on net power consumption in that roughness of a type that promotes lift of the charge tends to increase internal movement, internal friction, and consequently net power consumption.

Table 52. Effects of differences in the condition of the mill interior on power draft of ball mills (*after HS*)

6×16	*L*	25	260	292	325	25	
5×16	*O*	30	155	182	210	35	33
5×16	*L*	30	174	204	235	35	

a 3 1/2 in. thick. *b* 3/4 in. thick for 7-ft. mill, 1/2-in. thick for others.
c $P_1/P_2 = D_1^{2.6}/D_2^{2.6}$ *O* Overflow-type. *L* Low-level.

Pulp level in a continuous mill is a function of relative diameters of feed and discharge openings, of length, and of pulp viscosity. The higher the level, all other things being constant, the less the net power consumption, since high level lowers the density of the charge, shortens the lever arm, and lubricates a higher percentage of the total surface of the tumbling media. Hence, all other things being equal, net power consumption per ton of tumbling charge in open-end mills is higher than in overflow types, is higher in short mills than in long, is higher with coarse feeds than with fine, with hard and angular pulps than with the reverse, and is a minimum with pulps of maximum lubricating capacity, which normally corresponds to an intermediate pulp density. If, however, the pulp is so dense as to constitute a thick paste, the effect is to prevent internal movement of the charge and to lubricate the breast of the mill, whereupon power consumption drops sharply (*112 A 37*).

Maximum power was drawn in laboratory mills (*112 A 35*) when the volume of pulp in the mill was just sufficient to fill the interstices in the tumbling media with the mill at rest. The quantity of pulp for maximum power draft increased slightly with increases in ball load and r.p.m. of mill when using ribbed liners. With smooth liners at high speeds—90 to 100% of critical—however, power draft was minimum with the pulp load equal to the interstitial volume.

Power per ton of tumbling charge is greater, all other things being equal, with rods than with balls, and greater with balls than with pebbles; it increases with diameter of mill, is higher in cylindrical than conical mills, is higher in short than in long mills, is higher with rough than with smooth liners, and with low than with high discharge. For power consumption under various conditions of practice see ***Power consumption*** in Arts. 7 to 11.

Cost of power is from 50 to 60% of grinding cost in the majority of plants, and grinding power exceeds 50% of total power at many mills. For purposes of rough estimate a price of 1¢ per kw-hr. is safe.

16. PULP DENSITY

Pulp density affects time per pass, internal friction of load, load friction at liner surface, and the buoyant and spreading effects of the pulp on the tumbling media. Through these primary actions it influences capacity, grind, and power consumption.

The operating requirement is flow of solid over the surface of the tumbling media; the desideratum is uniform flow over all of the surface. This is best met by a pulp thick enough to maintain substantial homogeneity and thin enough to flow readily under a relatively small head.

Perfectly dry rock, when ground fine, is surprisingly fluid, flows readily through a cylinder mill, and has great transporting power. When the moisture content is between 8 and 15%, or thereabouts, especially if the solid contains clayey matter, a stiff mud is formed that cannot be forced through the mill and effectually prevents operation. With upward of 20% moisture, ordinary pulps are sufficiently fluid to pass through the mill readily, the fluidity increasing with increase in moisture content. For a given moisture content the apparent wetness is greater the coarser the solid particles, and viscosity is correspondingly lower.

Operation is guided by the appearance and feel of the pulp. As a first approximation, it should look and feel like molasses. From this starting point, the requirements of the operation and the character of the ore determine whether the molasses shall be thick or thin. The range is normally between 60 and 80% of solids, trending generally toward the higher figure for coarse granular feeds and high circulating loads and *vice versa*. Table 54

a H, Highest figure; *L*, lowest figure; *A*, average.

summarizes reported data. The relatively low averages for the rod mill are because it usually operates as a primary, frequently in open-circuit, and hence the mill feed, although coarse, carries a relatively high percentage of primary slime and requires a correspondingly large amount of water to give the desired fluidity. The high figures and the relatively high averages for the ball mills in fine grinding correspond to high circulating loads and mill feeds from which slime has been removed by feeding the circuit through the classifier. The lower average for the tube mills is because the pulp in the mill averages uniformly fine, a lower percentage of solid produces the desired molasseslike consistency, and with the smaller (and sometimes specifically lighter) tumbling media, transport effect must be kept down to prevent excessive rejection of media in overflow mills, or clogging in grate mills. On the basis of available fall through the mill, it should be possible to carry thicker pulps in a grate mill than in an overflow mill; tendency to clog grates with thick pulps militates against such practice, however, and Table 54 indicates no such trend.

In considering the reported figures it must be borne in mind that the averages contemplate ores of average specific gravity. In a particular case, with an ore of nonaverage specific gravity, comparative volumes should be considered.

Departure from optimum density conditions has considerable effect on grind and capacity. Table 55 shows that while high moisture content will maintain rapid flow through

an overflow mill and cause greater reduction of 3/8-in.~10-m. sizes from 3/8-in. feed in a single-pass operation than will occur with a thicker pulp, the latter causes more production of the desired fine sizes with less power per ton. Table 56 tells a similar story for closed-circuit operation in a grate mill on a similar feed. Table 57 shows the importance, in fine grinding, of close control of density. Feed rate was constant. There is a definite optimum in production of <325-m. at 63% solids; below this figure the balls were not well coated; above it the small balls were cushioned; further increase caused them to float to the grates and clog them, whereupon both capacity and grinding fell off sharply.

a <3/8-in.

Pebble loads require thinner pulps than ball charges.

Maxson (*134 A 319*) states that critical (optimum) pulp density, ball size, and mill speed are interdependent.

At Asturiana de Minas (*115 J 396*) when a 4.9-ft. (diam.) conical mill with 2-ton ball load was fed with <2-in. feed at the rate of 50 tons per 24 hr., the product with 70% solids contained 1% >2-mm., 83% <40-m., and 17% <200-m.; while with 50% solids the corresponding quantities were trace, 92%, and 28%. The experimenter found that decrease in solids to 20% caused further increase in fineness of discharge, and that progressive thickening above 70% solids caused production of a progressively coarser product until grinding ceased altogether. At Catemu (*123 P 886*) a 4 1/2-ft. × 16-in. conical mill was operated over the range of 60 to 80% solids. The best results were obtained at about 65% with soft, clayey ore and 70% with hard, compact ore. When solid content rose above 70%, the mill discharged much coarse material.

The higher viscosity and stickiness imparted to the pulp by clayey slimes are frequently utilized intentionally. Thus at ANACONDA, when difficulty was encountered in getting coarse feed through a mill trunnion, a part of the mill discharge, which was definitely viscous, was cut back to the feed; this eliminated choking despite that the total tonnage passed through the feed trunnion was more than tripled. At ROAN ANTELOPE introduction of primary slimes to the finishing mills increased capacity and decreased steel consumption by causing better coating of balls. At BALMAT direct feed to the primary mills as opposed to introduction of new feed into the primary classifier increased capacity in the circuit and decreased steel consumption. If a high grind-per-pass is desired, pulp should be relatively thin, but under these circumstances there will be considerable overgrinding unless feed rate is correspondingly increased. In grinding Cornwall tin ores, where it is desired to free cassiterite but not round off the grains, dilute pulps are reported best. At ALASKA-JUNEAU (*IC 6757*) a thin pulp and high feed rate were employed to prevent overgrinding. Wartenweiler (*37 JCM 114*) reports that in grinding pyritic concentrate on the Rand to 90% <325-m. results were poor until the pulp in the mill was raised to 75 to 80% solids.

Power. Maxson *et al.* (*112 A 130*) state that the capacity of a given mill grinding wet is from 1 1/2 times to twice that in dry grinding. The difference is due largely to the greater volume of the dry interstitial solid corresponding to a given feed rate, and the consequent mass resistance to a sufficiently close approach of the grinding media to effect steel-particle-steel crushing systems. In general, the thicker a liquid pulp up to the point of stickiness, the higher the capacity. The controlling link here is the amount of in-load and load-shell friction. The higher the load center is maintained, the greater the torque, the greater the power draft, and, consequently, the greater the amount of grinding, up to the point that the tumbling media are forced apart to an extent that prevents steel-particle-steel grinding. If a pulp becomes unctuous before it becomes sticky, it lubricates the load, whereupon there is a drop in power draft and a fall in grinding.

Steel consumption is consistently lower with thick pulps (*IC 6757*).

Addition of water. In most cases water is added to the mill to bring pulp to the proper consistency. Commonly this water is necessary to make the classifier-sand return flow in the launder. Dowsett (*108 J 185*) recommends that, in conical mills, at least, as much of the new water as possible be added from the discharge end about 1 1/2 to 2 ft. back in the discharge cone. This increases the fluidity of the pulp in this part of the mill and lessens discharge of oversize.

17. EFFICIENCY

Unlocking. Since the function of fine comminution in an ore-treatment plant is to liberate the valuable mineral, the ultimate measure of performance is the extent to which such unlocking is attained, and the ultimate measure of efficiency is the relative over-all cost of such attainment. In the nature of things, however, it is impossible to set up either of these measures as an operating control. The existence of a correlation between the percentage ground through (or retained on) some key size and the metallurgical recovery has been pointed out (Art. 13). Furthermore, since power comprises upward of 60% of operating cost, and steel consumption, which makes up most of the balance, tends to parallel power consumption, the tonnage ground through the key mesh per unit of energy input makes a satisfactory substitute measure of efficiency. The key mesh may be the *mog*, but the releasing mesh, as indicated by deviation from the distribution line and confirmed by microscope, is more informative. Instead of dollars or power, the denominator of the efficiency equation may be mills or tons of tumbling charge.

Effective unlocking, from a concentrating standpoint, is measured by the money integral of recovery and grade of concentrate when the ground product is concentrated in the plant or in a correlated laboratory test. A similar measure applies to exposure for leaching processes. Such tests should be made for a series of grinds to determine both the key mesh and the percentage passing it that shows optimum return per unit of cost. This then represents optimum performance. Both deficit and excess in percentage of material passing the key mesh represent inferior performances. Deficit shows up directly, if the efficiency statement is in the form of tons produced through the key mesh per hp-hr. Excess should, if possible, be correlated with deficit in such a way that excess percentage through can be calculated as percentage retained on the key mesh and added to the actual percentage determined by sizing test.

Key-mesh efficiency has the disadvantage for comparative purposes that it is dependent upon the ore, both from the standpoint of grindability and that of dispersion of valuable mineral therein, but it is informative as to machines when applied to runs on the same ore, and as to ores when applied to analogous performances of the same machine thereon.

New surface produced would be, if it were determinate, the measure *par excellence* of effective performance in grinding many industrial minerals and products because their subsequent utility is a function of their specific surface. Correlation between surface and

value similar to that for liberation and recovery could then be set up. Actual surface of comminuted products cannot, however, be measured, nor the extent of approximation determined with certainty. But comparative measures of various behaviors of comminuted products can be made, on the basis of which approximations to specific surface that are relative between themselves may be founded (Sec. 19, Art. 17).

Several investigators have used such surface approximations as the basis for measuring grinding efficiency in ore-treatment plants. The method has no utility in such service. It gives the bulk of the performance credit to the sizes ground beyond the useful liberating sizes, in other words, to the wasted work. Coghill (*126 J 934*) attempted to escape this fault by artificial ascription to all material below the useful release size of the surface factor of the size below such useful size (Sec. 19, Art. 19). This reduces the credit for useless work but applies no penalty to that part of it which is harmful. Furthermore, as modified, the calculated new surface produced varies substantially directly with the percentage passing the release screen. Hence the method yields no more information than is obtained by using the weight passing key screen as the basis, and it involves an additional calculation.

Work of crushing. The researches of Martin, Gross and Zimmerley, Dean *et al.*, Owens, Andrews, and others (Sec. 19, Art. 11) have indicated that if the work that is done in crushing by deforming particles without producing break is disregarded, net energy input in near-frictionless simple crushing machines is proportional to new surface produced, as estimated by various methods of approximation. But since such ineffective deformation is an essential part of all breaking other, perhaps, than that in high-speed impact machines, it is a part of the necessary work that must be done to crush. Furthermore, from the necessary mechanics of the situation, it varies as the volume of the particle broken. That part of it which does not go into producing a break is largely transformed into heat on elastic restitution of the particle. The relatively great magnitude of the heat effect in grinding as compared with that in coarse and intermediate crushing indicates a much larger amount of deformation and restitution in the former operation. Hence, in so far as the straight-line correlation of estimated energy inputs with approximated surface production is interpreted to mean that the work done in crushing is measured by the new surface produced, it is, in the author's opinion, unsound. It is fortunate that operators are not dependent, for commercial measures of the effectiveness of their grinding operations, on actual mechanical efficiencies.

Comparison of comminuting performances. Despite the inadequacy of estimated surface as a measure of useful liberation, exposure, or energy expended, it has some possible value as a comparative measure of the comminution effected, for the reason that it supplies an understandable common denominator for integrating screen grades, and, by use of Gaudin's distribution law as applied by Bond and Maxson (Sec. 19, Art. 19), it permits estimation of the surface in subsieve sizes without the necessity of performing the actual gradings. By relating it to energy input for different operations, the estimated amounts of new surface per unit of gross energy input may be calculated. This has an apparent comparative value if it be borne in mind at all times that at least three independent variables—grindability of the material, reduction range, and machine performance—are lumped together in the answer. By keeping two of these constant in any given case, an actual, although probably not an accurate, comparison is possible.

Bond and Maxson (*134 A 316*) indicate that reduction range does not have a great effect when considering one machine, in that they found that the estimated new surface produced per revolution of a laboratory batch mill (*i.e.*, per unit of gross energy input) remained substantially constant through a considerable range in circulating load and *mog*.

Performances are measured in the great majority of mills in terms of tons per hp-hr. to a particular *mog* or tons <200-m. produced per hp-hr. Such measures for a large number of plants are given in the performance tables in Arts. 7 to 11, *q.v.* The range in flotation mills, the majority of which are grinding to substantially 48 *mog*, is roughly from 0.04 to 0.08 tons <200-m. produced per hp-hr. with the average close to 0.055 tons per hp-hr. In all-slime cyanide mills grinding to 100 or 200 *mog*, and therefore faced in most cases with grinding of hard gangue grains, efficiencies thus measured tend to be less than half of those in the flotation plants.

18. ATTENDANCE AND CONTROL

The operator of a grinding mill can control, ordinarily, the new-feed rate, the tumbling charge, the density of the mill discharge, and the density of the classifier overflow. The usual variables that are outside his control are the characteristics of the mill feed as regards size, grindability, mineral content, and mineral distribution. Hence, his job is to so vary his controls as to produce optimum results from the standpoints: first, of metallurgy; second, of tonnage; third, of grinding efficiency. What part of the decision as to results is left in his hands depends in part on the size of the plant and in part on the man-

agement. In a small plant the mill operator may be also the concentrator man, in which case he will normally use his own judgment as to the changes to be made in ground product to satisfy prescribed metallurgical limits. In a large mill, on the contrary, the nature of the ground product will be prescribed within relatively close limits, usually both as to size and pulp density, and the operator's freedom will be practically limited to changes in new-feed rate and density of mill discharge.

The effects of the various changes in operating conditions available are discussed elsewhere.

Number of mills per operator depends primarily on the size of plant and the number, type, and effectiveness of the control devices installed. With an easily controlled mechanical feeder on the mill bin; clean water under a constant head, and reasonably accurate valves on the supply line; accurate and easily read ammeters on the motors and a constant voltage; and new-feed supply that is reasonably uniform in mineral content, limiting size, and size distribution; an experienced operator can handle 10 to 20 primary mills or perhaps double the number of secondary mills, except that, when one man is attending to a large number of mills, the charging of make-up tumbling media must be handled by a roustabout or by special mechanical charging devices provided. In general, with less than 10 mills in a plant, all of them are attended by one man, and with three mills or less, the mill attendance is a minor part of the operator's duties.

Control Devices

Feeders. There should be a separate feeder at the mill bin for each mill. It should be one capable of relatively constant delivery within close limits, and readily adjustable as to rate, preferably by remote control unless the bin is close to the mill (see Sec. 18, Art. 22). It is well to provide prominent telltales both as to depth of charge in the bin and absence of rock on the feed conveyor. Such gadgets are usually the product of local ingenuity.

Weighing of section feed is usually done by automatic scales (Sec. 18, Art. 23; Sec. 19, Art. 4) on the conveyor from the feeder to the mill. Constant-weight feeders are available, as are also electrical controls from weigher to feeder. In general, however, it is better to control feed rate from the mill itself, either automatically (see below) or through the intervention of the operator.

Mill control is normally through a chain of events started by the operator in response to some change in circuit operation. The indicators of change in the circuit are sound of the mill, power draft, and tonnage of circulating load; occasionally temperature of mill discharge.

Sound. A skillful operator can judge the interstitial loading in a mill by the sound made by the tumbling charge and, if the density of the effluent is correct, can bring the sound back to normal by suitable variation of feed rate. Diminution of sound indicates decrease in nearness of approach of tumbling media to each other, caused either by a coarser feed or greater throughput. In open-circuit grinding either condition invariably correlates with coarser discharge. The converse likewise holds. In closed-circuit work, however, it is, of course, possible to vary throughput and consequent noise considerably without change in fineness of product by change in circulating-load ratio. But once a given throughput and a given composite feed size have been set as constituting normal operation, departure therefrom produces a difference in sound and size of product.

Electric ear (Manufacturer: Hardinge Co.) is a radio-electric device adapted to translate differences in mill sound automatically into changes in feed rate (*134 A 371*). It comprises a microphone, which is set up near the mill shell; a box containing suitable relays to actuate a switch on the feeder motor; and a panel board carrying a microammeter, which indicates relative sound level at the microphone, a calibrated dial for regulation of the relays to response at a desired sound level, and pilot lights indicating power in the lines to the feeder motor and the ear circuit. For details of the electrical circuit see *U. S. Patent 2 235 928.*

In normal operation, with a new feed of relatively constant composition and size distribution, the feeder motor is "on" for 10- to 60-sec. intervals and the "off" periods are 2 to 20 sec. A recording ammeter may be placed on the feeder-motor line to indicate feeder activity. By using an electrically actuated valve on the line supplying mill-feed water, and connecting it in parallel with the feeder motor, pulp density of new feed is also under automatic control. Placing a surge tank between the valve and the mill with a manual valve between the surge tank and the mill to maintain an average head in the tank will smooth out the water supply while maintaining the desired pulp density.

Table 58 presents grinding performance at International Nickel with electric-ear control on a $6\,1/2 \times 12\,1/2$-ft. (I.D.) open-end ball mill running at 23.1 r.p.m. in closed circuit with a 12-ft. Dorr FX classifier. New feed was $<3/16$-in. The performance without automatic control for the month preceding the tabulated operations averaged 47.7 tons new feed per hr. to 15% $>$65-m., corresponding

to 0.145 ton new feed per hp-hr. It will be noted that the operator-controlled run corresponds most closely to automatic runs 4 and 5 except that these, with a somewhat higher feed rate, made a finer product. As compared with runs 2, 3, and 8, at what appear to be the optimum dial setting, the automatic runs average 13% increase in tonnage of new feed to the same *mog* and about 10% more tons new feed per hp-hr. SLADEN-MALARTIC reports (*32*[1] *CIMM 170*) a similar increase in capacity to the same *mog*. At this plant the mill motor was the bottleneck; automatic control made possible operation at the maximum safe power draft.

Table 58. Ball-mill operation at International Nickel with electric-ear control

Power draft of a grinding-mill motor is relatively responsive to changes in conditions in the mill. The Hollinger staff (*HS*) characterize the indication as very accurate. The Lake Shore staff (*LSS*) reported similarly. Hitzrot (*134 A 340*) states that this sensitivity is characteristic of low-level operation. If, therefore, a good ammeter is on the line, it can be used as an indicator to the operator of the necessity for a change in operation. The internal conditions thus indicated are, of course, the total weight of material in the mill, the distance of its center of gravity from the axis of rotation, and the extent of upward displacement of the center of gravity caused by the mill rotation. Increase in interstitial loading, due to greater throughput, in the usual operating range, lowers the power draft because the inward movement of the center of gravity is greater, proportionately, than the increased weight. A continuing decrease indicates a continuing build-up in throughput and eventually results in complete overload and cessation of grinding. Drop in the reading with a constant throughput indicates either a decrease in tumbling charge or an increase in pulp density. There is a gradual change in draft with liner wear. The initial change may be a fall as the liner smooths down. Thereafter there is a slow increase, if replacement of tumbling media is held constant irrespective of change in mill volume, due to increase in lever arm of the load; and a more rapid increase, if load is held to a constant percentage of mill volume.

At HOLLINGER (*ibid.*) ammeter control takes care of variations in fineness of new feed; with finer feed more is ground out per pass, less returns, the ammeter reading rises, and the operator increases the new-feed rate to bring the reading down to normal. A continued variation of 1 to 2% in the mean of the ammeter swings is significant. The classifier follows the mill without control other than that necessary to maintain constant density of overflow.

Temperature of mill discharge, as judged by feel, was used as a control for a considerable time at NEVADA CONSOLIDATED (*46 IMM 589*). Apart from the unreliability of the nerves of feel as indicators of temperature—which could, of course, have been obviated—a fall in temperature indicated either an increase in total throughput or a relative increase in liquid throughput (decrease in pulp density), the remedies for which are different.

Tonnage of circulating load is measured either by eye or by some more positive method, *e.g.*, weighing tanks and diversion splitters, as at HOLLINGER (*HS*), or by indicating or recording ammeters on the classifier motor, as at CUBAN AMERICAN MANGANESE (*153 A 98*). With a feed of constant grindability characteristics the method is reasonably sensitive, if the tonnage determination is accurate. But comparison of tests 2 and 3, Table 58, indicates that with variation in grindability (% S) an increase of 19% in tonnage of circulating load was necessary to maintain grind at the same time that tonnage of new feed was dropped 5.3%.

Other grinding-circuit controls. At HOLLINGER (*HS*), in addition to the ammeter on the mill motor and the arrangement for tonnage-sampling classifier sand, there is a recording scale on the feed belt, remote control on the feeders at the bin from the ball-mill floor, a pressure gage on the solution feed line, and a gravity scale for determining density of classifier overflow. At CUBAN-AMERICAN MANGANESE (*loc. cit.*) automatic density controllers on the classifiers, recording meters on the classifier-motor circuit calibrated to read tons of circulating load, and rheostats governing the speed of the motors driving the apron feeders at the ore bins, all located in the control room, comprise the operating control of the grinding circuit; change in the setting of the density controller changes product size; change in the feeder speed, as indicated necessary by the circulating-load record, permits maintenance of constant size of classifier overflow by compensation for variations in hardness of ore, size variation due to bin segregation, etc. A common gadget used to warn an operator of failure of feed comprises a drag which rides the load on the feed belt, the drop of which, with no load, closes a switch which sounds a horn or bell, and/or lights a warning light, and may record the time of interruption (*138 ¥ 11 J 42*).

Instrument *vs.* sense control. An operator will almost invariably play safe in his settings when they are made by sense control. If, therefore, maximum tonnage is the aim, instrument control should always be provided. Concomitant gain in power and steel consumption and, possibly, operator efficiency, will more than pay the installation cost.

19. MAINTENANCE

The principal items of maintenance are the tumbling load, liners, grates, and feeders.

Rods. Charging of rods requires stoppage of the mill. It is, therefore, done at intervals spaced as far apart as is possible consistent with maintained capacity. The usual interval varies, according to the tonnage per mill, from 2 days to a week. The shutdown period varies according to procedure. With adequate crane service, a large discharge opening, plenty of room in front of the mill, and no necessity to remove worn rods, charging can be done in 10 or 20 min. by wiring the rods into bundles of 4 to 8 and clipping the binding wires after introduction, or by use of special slings or carriages (see *131 J 360*). At the other end of the scale, with no crane, and when worn and bent rods are removed at the same time, the shutdown period may be several hours. Under such circumstances the advisability of using rods of sufficiently high carbon content to cause them to break up rather than bend as they grow thin becomes apparent.

Balls are charged at short intervals as a part of regular operating routine. In smaller plants such charging is done each shift by the operator; in larger plants it is usually done on day shift by a roustabout. In OVERFLOW MILLS charging is ordinarily through the discharge trunnion; with GRATE MILLS it must be through the feeder unless an overload hole in the center of the grate will serve. Large balls are handled individually in manual charging; small balls may be shoveled in. With crane service, special boats are used for discharge-end charging.

Pebbles are handled in the same way as balls when they are special durable flints, but when mine rock is used the tonnage is too large for this procedure. SOUTH AFRICAN practice is best developed. It comprises a special hopper for the pebble rock and gravity feed therefrom through a chute or pipe into a horizontal pipe entering the trunnion. Fig. 13 shows one form of arrangement.

Storage of tumbling media. Since consumption is from a considerable fraction of a ton per week up to several tons per day, according to size of plant, some provision should be made to expedite handling into and through the store yard. When crane service is available on the grinding floor, the usual procedure is to unload to piles or crude pens within the range of the floor crane or of a portable auxiliary. When cars are used for transporting balls from yard storage to the mill, attempt is made to place the ball pens in such a position that they can be loaded by gravity from railroad cars and unloaded by gravity into the floor cars, but since the tonnage is not great and the bulk is relatively even smaller, not much expense is justified in contriving such convenience.

Liners and grates. Relining is the principal cause of lost time in tumbling-mill operation. At the unusual best it requires a shift with the services of 6 or 8 men. More usually the time is 2 or 3 shifts without any reduction in the number of men per shift. Rail liners grouted in (*e.g.*, Britannia type, Art. 5) require 3 days because of the necessity to permit the cement to harden, but 3 men per shift can do the job. At plants where a considerable number of mills of the same size is used and heavy-duty cranes are available, it is customary to have an extra mill and two extra stands at the end of the grinding floor. When a liner is to be changed the pinion shaft is dropped away, the trunnion-bearing caps removed, and the mill is lifted, its load is dumped into the spare, and the latter is then put into the working line. Then relining can be done as a regular rather than as a rush job. Shutdown time

with such procedure may be less than 1 hr. Mills are then put as nearly as possible on a regular schedule of relining. If this is coupled with use of white-iron liners cast in company or local shops with remelting of scrap, considerable saving may be effected. Otherwise mills must be shut down for inspection at relatively short intervals as the time for relining, based on past performances, draws near.

Feeders. Usual procedure is to use replaceable manganese-steel tips on plate or cast-iron feeders, or to hard-surface the tips as needed, and to patch the body by welding so long as such patching is justified.

Lubrication. The points to be lubricated are the mill gear, pinion-shaft bearings, mill main bearings and, with direct connection, the reducing-gear unit. A different lubricant is required for each service. The initial selection should be made on the advice of the manufacturer of the machine, and behavior should be watched carefully until performance is established. Thereafter experimentation in consultation with the lubrication engineer of one of the larger oil companies may well be instituted. Consumption is not great, but protection and possible power reduction are important. When the best lubricants have been found, their properties should be tested, and subsequent purchases should be made on specification rather than on brand.

20. COST OF WET GRINDING IN TUMBLING MILLS

The cost of grinding depends upon the size of feed, size of product, grindability of the ore, the size of the installation, and the efficiency of the operation. The principal items of operating cost are power, steel, and labor. Average cost of power in mining districts is close to 1¢ per kw-hr. Power required may be estimated from the performance tables, Arts. 7 to 11. On average ore power is from 40 to 60% of total operating cost, labor from 5 to 10%, and steel the balance. On hard ores steel may comprise 50 to 60% of total cost. Prices of cast or forged-steel balls range from 3 to 5¢ per lb.; cast liner, 2 1/2 to 4¢; manganese liner, 10 to 15¢. Average total cost (1930's) for grinding to flotation size (including classification) was from 15 to 20¢ per ton, with a low of about 8¢ per ton at the large porphyry-copper plants and highs of 25 to 35¢ at some of the lead-zinc differential plants. These figures are irrespective of the number of stages, but the low figures ordinarily relate to 8- or 10-m. feed and should be debited with 4 to 8¢ per ton for fine crushing or rod milling from 1-in. to this size. For grinding to 100- or 200-m. costs are double to nearly four times those to rougher-flotation size. White (*32 JCM 98*) states that on the Rand the grinding cost varies as the square of the percentage of <200-m. in the product.

21. MISCELLANEOUS WET-GRINDING MACHINES

Grinding ores for wet concentration and for hydrometallurgical extraction is done exclusively in tumbling mills except in an occasional small plant built largely from junk piles. There are, however, industrial grinding problems either actually better solved by the discarded ore grinders, or so thought to be. Inclusion herein of brief descriptions of these machines and their performances is justified on this basis.

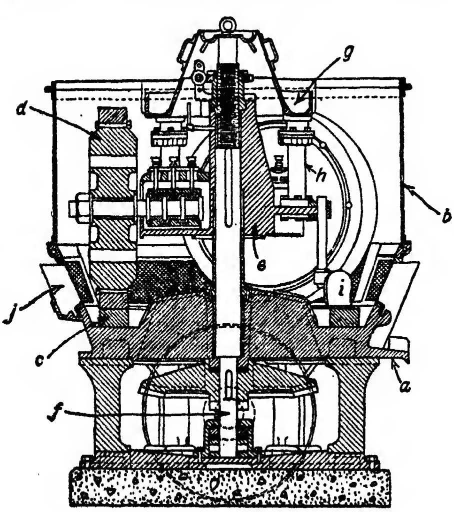

FIG. 78. High-speed Chilean mill.

Chilean Mill

A typical high-speed mill is shown in Fig. 78. The essential parts are a circular cast-iron pan *a* with screen and sheet-iron wall *b*, a die ring *c* and three steel-shod circular rollers *d*. The method of mounting and driving the rollers differs in different makes. In the figure, the rollers are rigidly mounted on axles carrying thrust bearings trunnion-mounted in an adjustable yoke *e* driven by feathers from spindle *f*. The vertical position of the yoke on the spindle is changed by means of nuts on the threaded upper portion. This per-

mits lowering the axles as the tires and die wear and also, by inclining the axles downward toward the spindle, utilizes, in crushing, a certain proportion of the centrifugal force developed. The feed stream, introduced into the annular box *g* is led by pipes *h* to a point just ahead of the advancing rollers. Scrapers *i*, following the rollers, churn up the material on the dies and help to keep the fines in suspension. Travel of the rollers causes a circular swash of pulp against the screen through which ground material discharges into the annular launder *j* and is led away. Each roller is free to lift independently when an uncrushable lump is encountered. In another form the thrust bearings are rigid in the yoke and the latter is carried on a spherical bearing on the spindle. The whole table tilts when one roller passes over a large particle. Both types of mill are made, infrequently, with overdrive and also with fixed axles and the journals in the roller hubs. Overdrive is clumsy and less rigid than underdrive. Hub journals are difficult to lubricate and protect against grit.

Sizes range from 2- to 8-ft. diameter, weighing 6,000 to 125,000 lb. respectively. The commoner sizes are the 5- and 6-ft., weighing respectively about 30,000 and 50,000 lb.

Low-speed mill. The modern form of low-speed mill has two to four rollers running on a die ring 6- to 10-ft. diameter. The rollers are made very heavy, or, in one form (LANE MILL) are on axles whose bearings are attached rigidly to the yoke while the latter carries a large tank that may be loaded with several tons of ore or pig iron in order to add to the crushing load. The SIZE OF PRODUCT is determined by the height of the overflow lip and moisture content, no screen being used.

Performances. HIGH-SPEED MILLS, 5- and 6-ft. diameter, ground relatively soft ores (porphyry copper) wet from about 3-m. to 10-m. at the rate of 150 to 225 t.p.d. with a consumption of 30 to 50 hp. Screen life was 1 to 10 days, the shorter lives corresponding to light-weight screens set low for high capacity. Shutdowns were frequent and maintenance costs high. The mills were displaced by rod mills.

LOW-SPEED MILLS, 6- or 7-ft. diameter, crushed medium to soft ores from 1- or 1 1/2-in. limiting to 35 to 65 *mog* at rates of 0.75 to 1 t.p.h. with a consumption of 10 to 15 hp. Upkeep was low and the machine essentially foolproof. It is adapted to inside amalgamation and is still used—and wisely—in some small gold mills.

For detail of operations on ores see *Ed. 1*.

Cost ranged from 10¢ per ton for reducing a soft ore from 1/4-in. to 10-m. to 25 or 30¢ for grinding medium ore from 1/2-in. to 20 or 28 *mog*, and ran up to 35 to 50¢ per ton for grinding medium to hard ores to 48 to 65 *mog*.

Arrastre

The arrastre is the primitive forerunner of the Chilean mill; it was much used in early Mexican gold milling for grinding from <1-in. size to slime. Practice in building varied, but the usual form was a circular pit, walled with rock or logs and chinked with clay, the bottom lined with flat stones similarly chinked, over which flat-bottomed cubical stones weighing 100 to 1,000 lb. were dragged by means of a horse-drawn sweep. Ground pulp overflowed through pipes at about 6 in. above the floor. Amalgamation was commonly practiced in the machine. CAPACITY varied from 200 or 300 lb. per day of soft ore in machines 3 or 4 ft. in diameter to 2 to 5 tons in 8- to 12-ft. mills.

Storms (*91 J 1053*) gives the following details of construction of the double arrastre shown in Fig. 79. Floor *a* was a double layer of 2-in. plank. Walls *b* were built of circular segments of 2-in. plank nailed together. The bottom of the basin was filled with a layer of firmly rammed clay, then 6 to 8 in. of sand in which the floor blocks of hard, tough stone were laid. The edges of the blocks were left rough so that the spaces between them would afford settling places for amalgam. The floor sloped about 1 in 8 toward the sluice gate, which was 6 in. wide, extended 4 in. below the top of the rock floor and was closed by a sliding door. The discharge height was varied by 1-in. strips laid in cleats. Drags weighed 800 to 1,000 lb. Massive diabase, diorite, or granite served well for both floors and drags. The drags were fastened to chains by 5/8-in. eyebolts wedged into holes 5 in. deep, and were set to sweep pulp into the path of the following stone. The front end of the drag stone should be lifted about 1 in. in order to nip large particles. The water wheel was of the hurdy-gurdy type; pipe line 7-in. diameter with 2-in. nozzle; water available, 18 cu. ft. per min. under 100-ft. head. Pinions were 3-ft. diameter with 13 hardwood pins 2-in. diameter, 4 in. high and 4 in. center-to-center. The horizontal pin wheels of 2-in. plank spiked and bound with strap iron were 6-ft. diameter with 51 pins similarly shaped and spaced. The main shaft revolved on 3-in. iron gudgeons. The bearing for the center post was made of 4-in. square steel 7 to 8 in. long with a spherical depression 3-in. diameter by 1 1/2 in. deep, smoothly finished, tempered at bronze color and set in the upper end of the lower post, which was

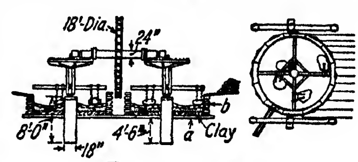

FIG. 79. Arrastre.

bound with an iron collar to prevent splitting. The gudgeon in the foot of the revolving post was forged to fit.

Operation. When amalgamating in this machine, batch operation was practiced. Ore was charged a little at a time with enough water to make a thin mud (40 to 60%) and ground for 5 to 7 hr., or until fine enough to add mercury, after which addition grinding was continued 2 or 3 hr. or until panning showed all free gold amalgamated. The speed of drags during amalgamation should not exceed 360 f.p.m.; higher speed could be used during crushing, but repairs were less when the desired capacity was attained with heavy drags and low speed. During the latter part of the amalgamation period the drags were slowed down to 150 f.p.m. and pulp diluted to allow coarse grains to settle and be ground and amalgam to settle in cracks. When panning showed the pulp free of amalgam, the basin was raked and sluiced out gently and the floor cleaned up in the usual manner (see Sec. 11, Art. 26).

Huntington Mill

Huntington mill (Fig. 80) consists of a cylindrical cast-iron tub *a*, 3 1/2- to 6-ft. diameter, with screened openings *b* in the walls to permit controlled egress of ground pulp; a die ring *c* wedged in place against the wall near the bottom; and four rollers *d* suspended like governor arms from the yoke *e* which is keyed onto the upper end of the driving

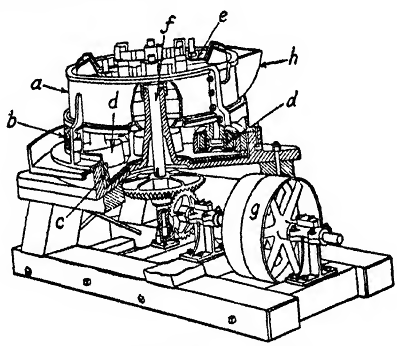

FIG. 80. Huntington mill.

spindle *f*. As *f* is revolved through bevel gearing from driving pulley *g*, the rollers (MULLERS) are pressed against the die ring by centrifugal force and roll around, crushing material between them and the dies. Feed is introduced with water at hopper *h*, the swirl set up by the revolving mullers throws it against the dies to be crushed and against the screens for discharge. The principal wearing parts are the roller tires, ring dies, and screens. Tires and dies are usually made of chrome steel. Screens are woven wire or punched plate. Sizes range from 3 1/2- to 6-ft. diameter of die ring; corresponding weights are from 7,000 to 50,000 lb.

Operation. SPEEDS are about 1,000 f.p.m. peripheral, usual practice was 75 to 85% moisture, which supplies sufficient water to wash material through the screens readily. FEED should be fine (0.25-in. or under) unless the ore is very soft. CAPACITY to 20-m. ranges from about 8 tons per 24 hr. for a 3 1/2-ft. mill with coarse (<0.75-in.) feed to as high as 185 tons in a heavy 6-ft. machine regrinding soft middling from 10- to 20-m. The product is granular and well suited to table concentration. COST at TONOPAH MINING CO. (*91 J 1213*) grinding through 28-m. rectangular mesh was $0.52 per ton, of which $0.21 was for repairs. Machine sectionalizes well.

Grinding Pan

The grinding pan (Fig. 81) consists essentially of a cast-iron tub, usually about 5 ft. diameter and 2 1/2 to 3 ft. deep, carrying a broad annular die ring on the bottom, on which heavy shoes are dragged by means of a yoke; this in turn is driven by a spindle from bevel gears and a belt-driven countershaft below the pan bottom. Shoes and dies are ordinarily of gray cast iron which wears down with a rough scored surface. White iron and alloy steels are unsuitable because the wearing faces become smooth and polished, with accompanying reduction in capacity. An adjusting screw with locking wheel is provided for adjustment of the height of shoes. Mullers, which carry the shoes, should be attached to the yoke arms by a flexible fitting in the nature of a universal joint; if a rigid joint like that in an amalgamating or clean-up pan is used, the shoes will often chatter,

capacity be reduced, and breakage increased. Die ring and shoe circle are sometimes continuous, but ordinary short spaces are left between both the shoes and the die segments. These form channels into which pulp flows and from which the crushing faces are fed. New shoes weigh 75 to 200 lb. and the crushing force is limited to that exerted by this weight when dragged over the die. Compensating weights are sometimes used to keep the crushing force up to normal as the shoes wear.

Pans are of two general types, *viz.*, ordinary and positive. In the ordinary pan the feed is introduced at any point, although preferably this is near the center, and discharge is by

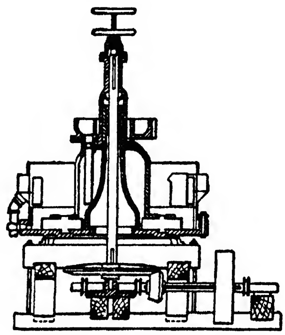

Fig. 81. Grinding pan.

peripheral overflow or its equivalent. Fineness of product is controlled by height of discharge. Baffles are placed on the inner wall of the pan to return pulp to the center. Capacity is low and power consumption relatively high on account of the large body of pulp that is kept in motion. The positive pan is fed through a central cylinder discharging near the bottom of the pan at the inner edge of the die ring. Pulp flows outward through the shoe and die channels and is then forced upward along the walls of the pan by centrifugal force induced by the swirling action. Discharge is low. Size of product is controlled by outside classification (or screening) or by a screen (Cobbe-Middleton), or a classifier (Forwood-Down) attached to the pan walls. Usual size range is 5- to 8-ft. diameter.

Operation. Speed ranges from 25 r.p.m. for 8-ft. pans to 50 or 60 for 5 ft. Capacity of the 5-ft. pan was from 1/2 to 1 t.p.h. from <10-m. to 48 or 65 *mog* according to character of ore. Power consumption for the 5-ft. pan was 8 to 10 hp. Metal consumption (cast iron) was 1 to 3 lb. per ton. Cost of grinding from 10-m. to 48 *mog* was 30 to 50¢ per ton.

Use. The pan has some present use in amalgamating concentrates, although most such work is now done in batch-type tumbling mills.

SECTION 6

DRY GRINDING

BY

HARLOWE HARDINGE, PRESIDENT, HARDINGE CO., INC.

1. INTRODUCTION

The primary factors that determine whether a material is to be ground wet or dry are: (*a*) Physical characteristics and subsequent use; (*b*) effect of material on the mill, *i.e.*, rate of wear, corrosive effect, tendency to pack or stick in the grinding zone; (*c*) shape, size range, particle distribution, and quality of the product desired; (*d*) relative economic efficiency of the operation, taking into consideration capital cost, power, labor, maintenance, repairs, and production; (*e*) climatic conditions; (*f*) availability of water supply; (*g*) nuisance and safety factors such as noise, dust, excessive vibration, and speed.

Those ores and industrial minerals which are best beneficiated wet are usually ground wet. Wet grinding has long been considered more efficient than dry, but recent developments in the arts of dry grinding and dry size separation have narrowed or extinguished any efficiency differential, so that now products heretofore ground wet are being ground dry at a lower over-all cost and/or to a product of such character as to increase the efficiency of subsequent processing or the salability of the product, or both. COAL used as powdered fuel is almost invariably ground dry, increasingly in units comprising grinder, a screen, and/or an air classifier, the coal being blown into the combustion zone by or together with the air used for size separation. The raw mix in a CEMENT plant may be ground wet or dry (Sec. 3A); the determining factor being, usually, the need for correction (Sec. 3A, Art. 2), but in some cases personal prejudice. Most of the new cement plants built in the 1920's used wet grinding for raw mix, but dry grinding with a modern air classifier makes a simpler and more compact installation, and again demands serious consideration (*45 #8 RP 49*). Dry grinding is essential for CEMENT CLINKER, since the cement must, of course, be kept free from water until used. In processing INDUSTRIAL MINERALS, the decision to grind wet or dry depends upon the character of product desired, the effect of metal contamination, and rate of mill wear. Abrasives are ground either wet or dry, according to the size and shape of grain demanded, more particularly, the mill wear. In grinding clays, mineral pigments, colors, and ceramic materials, decision may rest upon one prevailing factor or a combination of the factors mentioned above. METALLICS such as iron filings, aluminum, magnesium, and bronze are usually ground dry to avoid discoloration, oxidation or contamination. Magnesium powder for explosives, flares, etc., is usually ground dry because a more acceptable product is thus produced; magnesium may, however, be ground wet in some medium other than water, the liquid being distilled off later. Reclamation of metal particles from dross and waste in aluminum, magnesium, and brass foundries is accomplished by dry grinding, if practicable, owing to the simplicity of handling; but where jigs and tables are used for recovery, wet grinding is usual. Most SALTS, DRUGS, and the like must be ground dry, some in inert atmospheres to prevent explosion, others in definite chemical atmospheres to obtain the desired reaction, still others at very low or very high controlled temperatures; some are ground and mixed simultaneously; either batch or continuous operation may be employed.

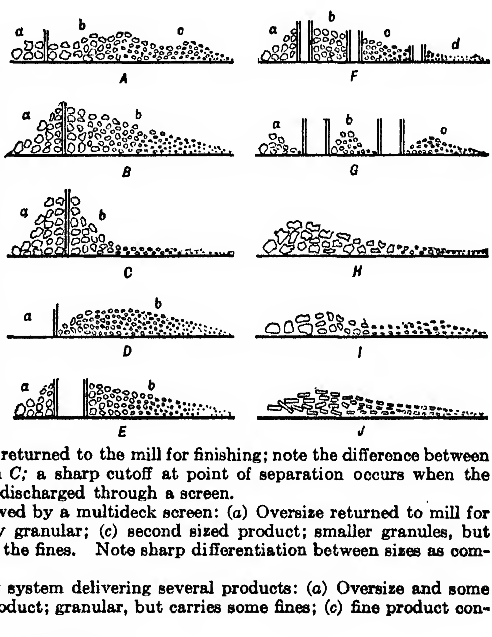
The decision to grind wet or dry is not, therefore, a simple question of efficiency or cost in all cases, but may be based upon factors that are not obvious at first glance, yet are vitally important to successful operation of the system as a whole.

Dry-Grinding Systems

There are three basic systems of dry grinding, *viz.*, (*1*) batch or intermittent, (*2*) open-circuit or single-pass, (*3*) closed-circuit. In BATCH GRINDING a charge of material is placed in the grinding device and remains there until the product is of the desired fineness, when it is removed in finished state. Tumbling mills are frequently run batch on small tonnages.

Open-circuit grinding mills have separate feed and discharge ports; feed rate is so regulated that the product is discharged in finished state. The attrition mill, buhr mill, pan mill, and tube mill are usually operated open-circuit. In closed-circuit grinding, part of the material passes through the mill more than once. After discharge it goes to a separating device, where oversize is removed and returned to the mill for further grinding, while finished fines are discharged from the circuit. The separation may be done within the mill itself, as in Krupp or Griffin mills with internal screens, or in roller mills with internal air classification. The external method is exemplified by a ball or pebble mill discharging to an external screen or air classifier which returns oversize; hammer, ball-bearing, and ring-roll mills are also thus operated.

Products obtained in grinding may be classified as: (*a*) graded, (*b*) granular, (*c*) fine, (*d*) abraded, (*e*) cleaned, (*f*) disintegrated or divided, (*g*) rounded, (*h*) sharp, or (*i*) flake. These various characteristics are illustrated in Fig. 1 (*26 IEC 1139*). The ideal product of



Legend for Fig. 1:

A. Open-circuit or batch grinding: (*a*) Particles coarser than specification; (*b*) the quantity of each size is variable; (*c*) an excess of extreme fines is present even though some oversize is permitted to discharge with the product.

B. Closed-circuit mill product prior to separation by air classifier or screen: (*a*) A relatively large amount of oversize is present; (*b*) grain size and quantity decrease uniformly.

C. Oversize removed by classifier (closed-circuit grinding): Oversize (*a*) together with a small quantity of undersize (*b*) is returned to the mill for finishing.

D. Finished product as discharged from air classifier: (*a*) Oversize is substantially eliminated; (*b*) finished product is reasonably uniform.

E. Division of product as discharged from a mill over a screen: (*a*) Oversize as returned to the mill for finishing; note the difference between this and oversize of the air classifier, item *C;* a sharp cutoff at point of separation occurs when the separation is by screen. (*b*) Product as discharged through a screen.

F. Multiple products from a mill followed by a multideck screen: (*a*) Oversize returned to mill for finishing; (*b*) first sized product, coarsely granular; (*c*) second sized product; smaller granules, but negligible fines; (*d*) some granules and all the fines. Note sharp differentiation between sizes as compared with air classifier, item *G.*

G. Products from multiple air-classifier system delivering several products: (*a*) Oversize and some fines returned to mill; (*b*) medium fine product; granular, but carries some fines; (*c*) fine product containing fines and superfines.

H. Granular particles, with sharp and angular grains.

I. Rounded particles produced in quantity in the finer sizes.

J. Flat particles; metals, graphite, mica; flaky in all sizes.

Fig. 1. Size distribution and shape of dry-ground products.

the method may not be procurable in a particular case because of the nature of the material and limitations of the mill used. Thus a multiple-size product (item *F*) might be desired, but be unattainable because the particular material blinded screens, or, as is more often the case, because fineness specifications required such fine grading that, although a screen would pass the material, screen-cloth maintenance would be prohibitive, and an air-classified product, (item *G*) would serve.

Material may be merely abraded, and thus cleaned, rather than ground. Some materials require disintegration to break away unwanted particles, *e.g.*, foundry waste, where it is desired to remove burned sand, ashes, and/or clinker from metal particles, so that the latter may be recovered, yet the operation must be such as to avoid grinding of the metal particles themselves.

Classification of mills

Grinding machines employed for dry pulverizing may be grouped into the following classes: (*a*) Attrition and buhr mills; (*b*) impact mills; (*c*) jet or injector-type mills; (*d*) pan or chaser mills; (*e*) rolls; (*f*) ring-roll and roller mills; (*g*) ball-bearing mills; (*h*) tumbling mills.

These mills may be further grouped into two classes characterized by the fact that in the machines of one group the comminuting elements are relatively few and follow definite paths (FIXED-PATH MILLS), while in the other the elements are multifarious, and not constrained as to individual path (TUMBLING MILLS).

2. FIXED-PATH MILLS

Buhr and attrition mills

Horizontal buhr mill (Fig. 2) is one of the oldest forms of grinding mill. It consists of two flat circular stones *a*, *b*, only one of which may rotate, or the two may rotate in opposite directions. In Fig. 2, *a* is fastened to housing *c*, held down by spring-backed bolts *d;* stone *b* is mounted on a rotary table driven by shaft *f* and pulley *g*. Spacing of the stones is effected by hand wheel *h* and lever *i*, which raises ball-bearing step *j*. Feed, introduced through hopper *k*, drops into the central hole, works its way to the outside while being ground between the stones, and discharges at *l*. Stones are made of rock emery or a combination of French buhr, pebble grit, and emery rock. Grooves are cut in the stones to force material toward the periphery; size and position of the grooves vary with the material being ground. SPEED of a 42-in. mill is about 300 r.p.m.; MOTOR HP., 18; CAPACITY, 1 to 3 t.p.h. according to material and fineness of product.

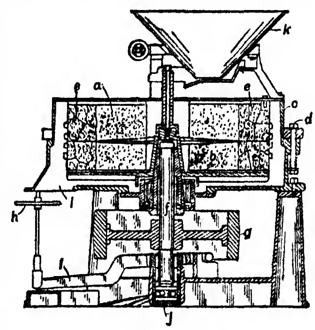


FIG. 2. Horizontal buhr mill.

Vertical buhr mill (Fig. 3) comprises a fixed stone *a*, and a rotating stone *b* carried on pulley-driven shaft *c*. Feed enters housing *d* via hopper *e*, and is introduced through the central hole in *a* by feed screw *f*. Ground material discharges at *g*. SIZE (diam. of stones) ranges from 24- to 42-in.; SPEED is 4,500 to 5,000 f.p.m. peripheral; CAPACITY ranges from $^1/_2$ to 15 t.p.h. according to size of mill, speed, material, and fineness of product; power consumption is 12 to 80 hp.

Use. Buhr mills are used primarily for grinding soft materials such as clay, chalk, talc, salt, coal, ocher, lime, and gypsum. Feed size should not exceed $1/_4$-in.; product ranges from 20-m. to 200-m., depending upon method of operation, grooving, speed, pressure, etc. It is recommended that for products finer than 80- or 100-m. screens or air classifiers be used to close circuit on the mills.

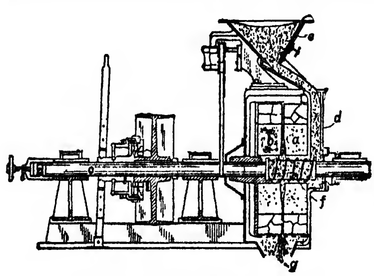

FIG. 3. Vertical buhr mill.

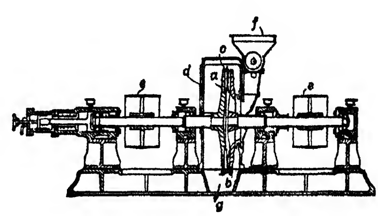

FIG. 4. Attrition mill.

Buhr mills have been largely superseded, as it is costly to dress the stones and difficult to obtain skilled dressers. Hard substances in the feed damage the stones despite provisions to permit them to spread in case foreign material enters. Efficiency is low; they become hot when grinding is fine; but it is claimed that with some materials a grade of product is secured that is not produced by other types of machines.

Vertical attrition mill (Fig. 4) comprises plates *a* and *b*, shod with grooved wearing rings *c*, all enclosed in housing *d*, and rotated in opposite directions by pulleys *e*. Feed is introduced centrally through hopper *f;* peripheral discharge emerges through outlet *g*. Grinding faces are made in different patterns to obtain products of different characters. SIZES (diam. of plates) range from 16- to 36-in.; SPEEDS range from 7,500 to 12,500 f.p.m. peripheral; power consumption: 5 to 35 hp.; CAPACITIES are low.

This mill is used principally for cracking and shredding plant products; it should, however, be useful for the softer industrial minerals when similar comminuting action is desired.

Impact mills

Hammer mill. For description and use as an intermediate crusher see Sec. 4, Art. 9 Some types are capable of grinding service when run in closed circuit with fine screens and/or air classifiers. CAPACITIES with 1/8-in. bar spacings on different materials as given by one manufacturer are shown in Table 1.

Table 1. Capacity of open-circuit hammer mill in grinding service (*after Jeffrey Mfg. Co.*)

Size, diam. of hammer circle by length, in.	Approx. hp. consumed	Tons per hour			
		Limestone	Coal	Burnt lime	Gypsum
20×12	12 to 20	2 to 2 1/2	2 to 3	3 to 4	3 to 3 1/2
24×20	30 to 40	4 to 5	6 to 8	7 to 8	6 to 7
36×24	60 to 75	10 to 12	14 to 16	15 to 20	15 to 18
42×36	100 to 125	20 to 25	30 to 40	35 to 40	30 to 35
42×66	175 to 250	50 to 60	75 to 85	70 to 80	65 to 75

Performances in grinding service are shown in Table 18, items 69, 84, 149, 178, 179, 209.

FINENESS of product is determined not only by the bar spacing, but by the SPEED. A 24-in. pulverizer at 1,000 r.p.m., grinding limestone, with 1/8-in. bar spacing, made a product 99% <6-m., 28% <100-m.; at 1,600 r.p.m., the product was 100% <6-m. with 43% <100-m. See also Table 18, item 149.

Raymond Imp mill (Fig. 5) is of the hammer type, adapted to fine grinding in closed circuit with a screen or air classifier. Feed enters the hammer chamber *c* through hopper *a* and star feeder *b;* ground product is swept out by an air current induced by centrifugal fan *d*, taking suction through pipe *e*, and leaves by pipe *f*. Blades *g*, adjustable, and mounted on shaft *h*, throw coarse oversize back into chamber *c*, which has the result of saving fan *d*, and decreasing transport load on the air. Fig. 6 shows an arrangement of the mill in a circuit in which the solid is subjected to hot gas during grinding. In this set-up the mill fan *a* takes suction through flue *b* on furnace *c* and delivers through flue *d* to cyclone collector *e*, from which finished product drops to bin *f*, while dust passes on into dust collectors *g* exhausted by fan *h*. Stack *i* is used in starting. Such an arrangement is commonly used for calcining gypsum or copper sulphate, etc., as well as for drying. As a unit grinder for powdering very soft coal in lime or cement plants, *d* is run to the burner, and *b* takes suction on the cooler (Sec. 3, Art. 24; Sec. 3A, Art. 4).

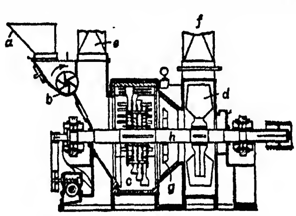

FIG. 5. Raymond Imp mill.

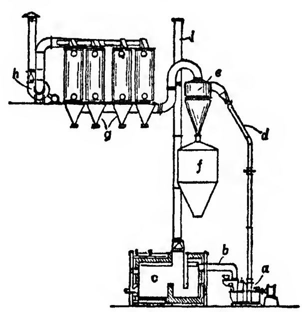

FIG. 6. Impact pulverizer in drying-grinding circuit.

This machine is suitable only for very soft materials. SIZES and CAPACITIES for a given service will best be determined by study of existing installations in similar service.

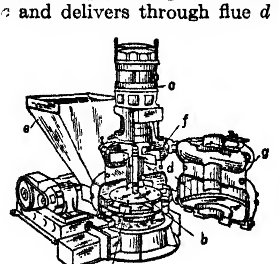

FIG. 7. Whiting horizontal-hammer mill.

Horizontal-hammer mill (Fig. 7), used primarily as a unit coal pulverizer, comprises hammers *a*, mounted on extended shaft *b* of vertical motor *c*, and corrugated cage ring *d* lining the chamber enclosing the hammer. Feed is introduced through hopper *e* into the side of the hammer chamber via a screw feeder. Fan *f* in chamber *g* takes suction through ports below the hammer chamber, and discharges

through a peripheral opening in the fan chamber. Fineness of product, dependent upon draft, is controlled by a deflector in the upper part of the hammer chamber. Rated CAPACITIES on bituminous coal (grindability 65 by Hardgrove method) range from 600 to 6,500 lb. per hr. to 70% <200-m.; corresponding MOTOR HP. ranges from 10 to 100.

Cage mill (Fig. 8), shown in open position, comprises two cages *a* and *b* revolving in opposite directions, one inside the other in the position assumed when the faces *c* of the housing are brought together. Feed introduced through screw feeder *d* (when the cover *e* is bolted in place over the cages) enters through the side *f* of the larger cage *b* into cage *a*, and is then thrown around inside *a* and between *a* and *b* until it escapes through bottom-discharge opening *g*. SIZES (diam. of larger cage) range from 12- to 54-in.; SPEEDS are from 4,000 to 6,000 f.p.m. peripheral; rated CAPACITIES are from 2 to 70 t.p.h. according to size of machine and character of feed.

Use. The machine is essentially a disintegrator of caked dried fine solids and very soft and/or brittle materials like phosphates, clay, salt cake, alum, pigments, and infusorial earth.

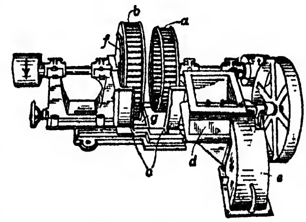

FIG. 8. Cage mill.

Jet Pulverizer (MICRONIZER), shown in Fig. 9, consists of a stationary squat circular grinding chamber *a*, top-fed through ports *b*, equally spaced, injected from feed manifold *c;* steam or gas at high velocity is introduced through peripheral jets *d* from manifold *e* along lines *i* tangent to circle *f*. Pressure of the entering fluid is transformed into velocity head by expansion to substantially atmospheric pressure within the grinding chamber. The force of these expanding streams, directed somewhat tangentially, causes the contents of the chamber to rotate at high speed, whereupon solid concentrates near the periphery and is acted upon by the entering gas. It is claimed (*45 CME 238*) that most of the energy of the gas is dissipated within an inch or two of the point of entry, causing intense local velocity gradients and violent collisions within the grinding zone. Most of the grinding action takes place within the mass itself, as evidenced by the fact that a rubber-lined grinding chamber has been employed without significant reduction in grinding efficiency. Even so, wear is relatively high. With certain materials, the wear may become excessive. Fine solid, crowded to the centrally located bottom outlet (diameter about one-third that of *a*) is in a rapidly whirling gas stream, and is thrown to the walls of collector *j*. It is claimed (*ibid.*) that efficiency of collection increases with intensity of classification in chamber *a*, so that degree of collection increases with decreasing particle size in the product, and that from 85 to 98% of the product is retained in the collector.

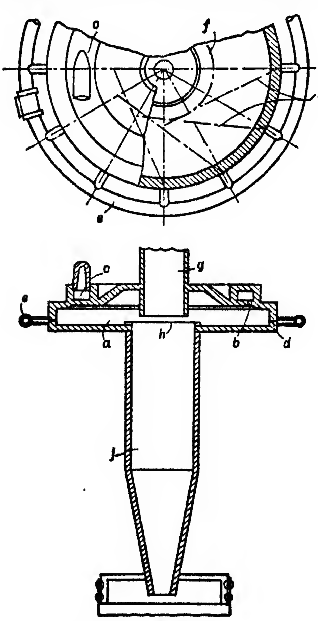

FIG. 9. Micronizer.

Steam is generally used where it can be applied, as it is more efficient, on a cost-per-pound basis, and will, also, make a finer particle size than air, but air is used when steam temperatures are not permissible. Air pressures are of the order of 100 p.s.i.; superheated-steam pressures range from 100 to 500 p.s.i. at temperatures of 500 to 700° F.

Chamber sizes range from 12- to 36-in. diameter by 1- to 2 1/2-in. axial height. Jet orifices range in number from 6 to 16, and in size from 1/8- to 3/8-in. SIZE OF FEED should not exceed 1/8-in. Rated CAPACITIES range from a few ounces to 4,000 lb. per hr.

Use. The economic range of application is limited to products considerably finer than 325-m., since the cost of grinding is excessive compared with methods commonly employed for coarser products. Very fine products in the micron sizes can be obtained, however, and, in a number of cases, products possessing special characteristics have been secured, so that the device is commercially successful but the field is limited.

The manufacturers state that to grind barite from 20-m. to <3μ, 3 lb. steam per lb. of feed is required; for talc through the same range, approximately 6 lb. steam per lb. of feed; grinding Persian Gulf Oxide to 2μ requires 5 lb. steam per lb. of feed; graphite ground to the same fineness requires 15 lb. steam per lb. of feed; most precipitated materials, however, *e.g.*, titanium dioxide, require only about 1 1/2 lb. steam per lb. of feed.

Pan Mill

Dry pan is also known as an EDGE-RUNNER or CHASER MILL, somewhat similar to the Chilean mill (Sec. 5, Art. 21) in basic principle. The form shown in Fig. 10 comprises a pan with sheet-iron wall (partly broken away) and perforated cast-plate bottom *a* which is rotated under rollers *b* by vertical shaft *c*. The roller axes may be supported so that the rollers do not actually touch the bottom plate, in which case it is the bed of material on the plate that causes their rotation and the consequent crushing. The crushing effect is increased by springs or hydraulic pressure exerted against upward movement of the shafts. Deflecting scrapers *d* move material under the runners.

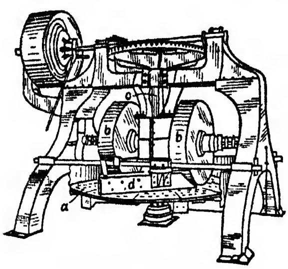

FIG. 10. Dry pan.

In another type, the bottom plates are imperforate and material discharges over the edge of the plate under baffles adjusted to a definite but close clearance. In yet another type the base is stationary and the rollers both revolve and rotate, the scraper also rotating to direct material under the runners.

RUNNERS and PLATES are usually made of wear-resisting steel or chilled iron; the plate is made of hard stone or porcelain, and the mullers of stone, if contamination by metal is not permissible. SIZES (diam. of pan) range from 5- to 10-ft. and mullers correspondingly from 7×36- to 13×54-in., weighing 1,750 to 8,300 lb. each. SPEEDS are 25 to 30 r.p.m. CAPACITIES on clay are from 1 to 15 t.p.h.; MOTORS, 10- to 60-hp. The rim-discharge machine is larger and heavier (16×60-in. @ 12,000-lb. mullers), is run faster (50 r.p.m.), and is rated at 40 to 75 t.p.h., but the product is coarser. Capacities with stone mullers are much lower; the operation is often batch, because no screen or perforated plate is employed, and rim discharge is not practical. The ceramic plate is usually 4 to 6 in. thick, and rolls 14×36- to 18×54-in.

Use is mainly in the clay and ceramic industries for mixing clays, disintegrating and grinding grog, and crushing quartz and other materials where relatively coarse pieces are to be crushed and metal contamination is to be avoided. Whereas the machine has a definite place in the clay-products industry, the ball and pebble mill compete, since maintenance and power consumption are high in the pan, particularly when a hard material must be ground fine.

Rolls

Choke-fed rolls (Sec. 4, Art. 8) may be used as pulverizers, and are so used occasionally, but probably in all cases some other machine would do the job better.

Performances. See Table 18, item 93, and Sec. 4, Art. 8.

Roller mills

These mills consist of a large metal ring against the inside of which one or more metal rollers of relatively small diameter press and roll and break solid particles introduced between the contacting surfaces. The mill takes a variety of forms with the ring either vertical or horizontal and pressure induced by gravity, springs, centrifugal force, or combinations of these.

Vertical ring-roll mills. The Kent Maxecon mill (Fig. 11) consists of a heavy floating ring *a* held in place by the three rollers *b*, which are pressed against the inner face of the ring by springs *c* mounted on a yoke holding the roll bearings, which pass through the sides of the housing. The upper roll only is driven; as it rotates, it rotates the ring, which rotates the other two rolls. Feed from hopper *d* is introduced through one side of the housing by chute *e*, which deposits it on the downgoing face of one of the lower rolls. Ring *a* rotates at a speed above critical, hence the material clings to the inner side until pushed off by a roll, usually after being partially ground. This product drops out through hopper *f*, ordinarily into a bucket elevator, thence to a screen or air classifier, which returns oversize.

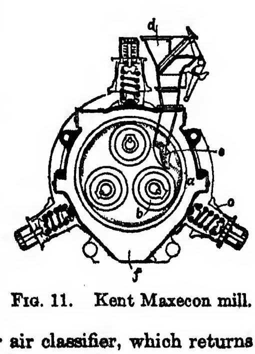

FIG. 11. Kent Maxecon mill.

Performance. See Table 18, items 38, 143, 144, 166.

Sturtevant ring-roll mill has a driven ring (Fig. 12, item *a*) actuated by a spider *b* on gear-driven shaft *c*. Rolls *d* are not driven, but rotate when pressed against the ring by springs *e* with pressures that range from 20,000 to 60,000 lb. SIZES (diam. × face of ring) range from 24×7-in. to 44×14-in.; rolls are 14- to 18-in. diameter; ring SPEEDS are 750 to 800 f.p.m. peripheral; MOTORS, 8 to 75 hp. Rated CAPACITIES for 45×8-in. mill are: barite from <1-in. to 40 *mog*, 8 to 10 t.p.h.; Florida pebble rock to 85% <60-m., 7 t.p.h., or 3 t.p.h. to 95% <100-m.; marble, 3 to 4 t.p.h. to 95% <100-m.

Product of this mill, which has no internal circulation, is relatively granular, particularly if a screen closes the circuit. Modern practice limits its range to between 20- and 80-*mog* for soft or medium-hard nonabrasive materials. POWER CONSUMPTION per ton of product is relatively low, but maintenance is high except on definitely nonabrasive feed.

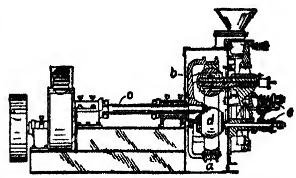

FIG. 12. Sturtevant ring-roll mill.

Horizontal-roller mills have horizontal rings, stationary or revolving, and rollers carried on shafts that are substantially vertical.

Williams mill (Fig. 13) comprises ring *A* mounted near the bottom of a high-sided cylindrical tub *B*, and 3 to 5 rollers *C* carried on shafts ball-suspended within housings *D*, which, in turn, are suspended off-center by pins *E* from yoke *F* on shaft *G* driven by bevel gearing *H* and pulley *I*. Centrifugal force pushes the rollers against the ring when shaft *G* revolves. New feed is introduced through hopper *J* at a rate controlled by star feeder *K*, and is pushed up into the crushing zone by pushers *L*, which rotate with the spindle.

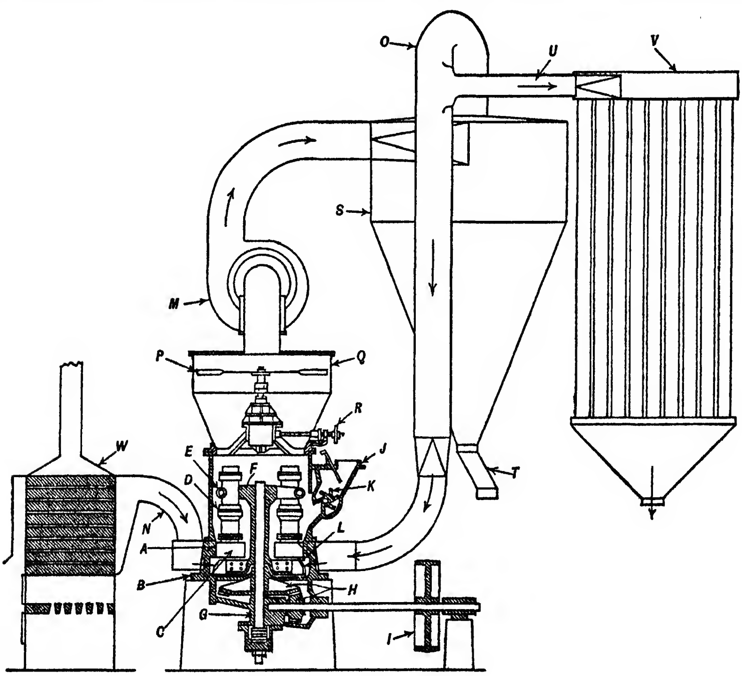

FIG. 13. Williams mill.

Ground material is exhausted by fan *M*, which draws new gas through pipe *N* and return gas through pipe *O* and thence upward through the grinding zone. Vanes *P*, rotating at adjustable speed and gear-driven from pulley *R*, set up a swirl in enlarged chamber *Q*, which throws coarser material against the chamber walls whence it slides back directly into the crushing zone. Fine solid drops out largely in cyclone *S* and is withdrawn through gas-lock *T*. Excess gas with some fine solid is bled off through *U* into air filter *V*. Hot gas may be supplied from furnace *W*, or other source.

Capacities of the standard mill, with a 50- or 60-hp. mill motor and 40-hp. fan motor, are given by the manufacturer as follows: Alum, ground to 99% <100-m., 2 t.p.h.; chalk, ground to 99% <325-m., 2 t.p.h.; lime, ground to 98% <200-m., 4 t.p.h.; pebble phosphate rock, ground to 6% <200-m., 6 t.p.h. The small size, with 15- or 20-hp. mill motor and 10 hp. on the fan, is rated at 12.5% of the production of the standard; and the large, with 125 to 200 hp. on the mill and 75 on the fan at 250% of standard.

Performances. See Table 18, items 10, 27, 118, 126, 158, 181, 184, 200.

Table 2. Sizes and capacities of Raymond roller mills on bituminous coal (*a*) (*Raymond Pulverizer Division, Combustion Eng. Co.*)

Maker's No.	Type	Product, % <200-m.	Capacity, lb. per hr.	Motor hp. Mill	Motor hp. Fan

73612	High-side	85	33,500	250	150

a Hardgrove grindability, 55; feed <1-in., allowable moisture 2% without mill drying, 5% with.

Raymond roller mill is similar in general construction. LOW-SIDE MILL utilizes the casing above the rollers as the separating chamber, substantially as in the Williams mill, wherefore product is relatively coarse; HIGH-SIDE MILL makes a rough separation in the bottom of the casing and final separation in the upper part.

RATED CAPACITIES are given in Table 2.

Performances are given in Table 18, items 13, 14, 15, 17, 66, 70, 71, 74, 76, 77, 112, 121, 122, 146–148, 163, 165, 168, 173, 174, 176, 177, 202, 205, 206.

Raymond bowl mill (Fig. 14) has been used extensively as a unit mill for coal pulverizing. It consists of bowl *a* rotated by a vertical shaft through reduction gearing *b* from the motor *c*, which also drives fan *j*. The face of the grinding ring is sloped outward upwardly about 20° from the vertical. Rollers *d* are spring-loaded, but an adjustable stop prevents contact with the ring. Feed enters via hopper *e* and, mounting the side of the ring, causes the rolls to rotate by taking up the clearance; at the same time it is crushed.

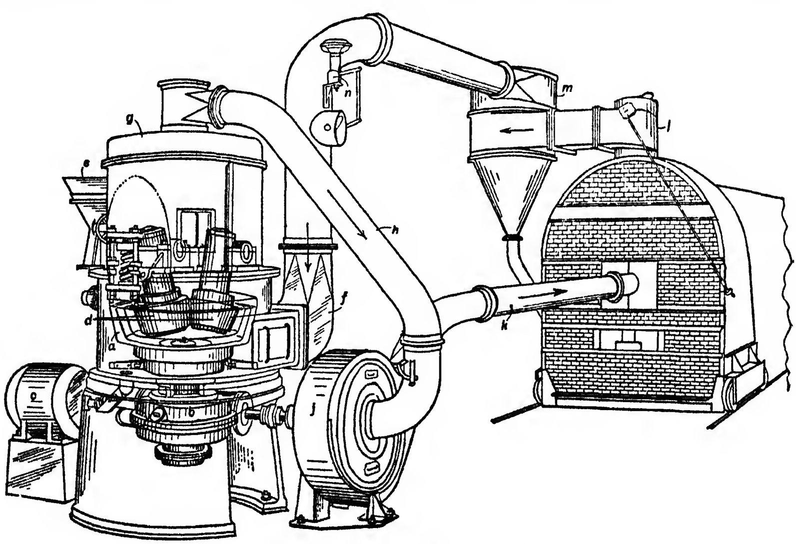

Fig. 14. Raymond bowl mill.

Material thrown over the periphery of the bowl enters an air stream, which comes in through pipe *f*. Oversize is dropped in the classifier in housing *g* (similar to *Q*, Fig. 13) and returns to the mill. Circulating load is estimated as high as 400 or 500%. Temperature in the mill itself is controlled automatically to about 175° F., the drop being due to the amount of heat absorbed in drying the coal. In grinding coal for unit firing of a kiln,

air from the recuperator, drawn through duct l, may have a temperature of 600° F. It is possible to dry and grind coal carrying as much as 15% moisture.

Ground coal and air from the classifier pass through pipe h, fan j, and directly into the kiln through pipe k.

Recuperator and kiln gases are often heavily laden with ash and grit, which may be removed by a dust trap m. Automatic temperature control in response to variation in heat consumption with variation in moisture content comprises a shutter at n on the incoming-air pipe, which is actuated by a temperature controller on a mill thermostat.

Catalogue data are given in Table 3.

Performances are shown in Table 18, items 75, 82.

a Grinding bituminous coal; Hardgrove grindability, 55; feed <1-in., 8% initial moisture; product, 70% <200-m.

Griffin mill (Fig. 15) has a fixed horizontal grinding ring a and a single roll b mounted on a long shaft depending from the driving head c. The roll is fixed rigidly to the long shaft; the shaft rotates in universal joint d. Rotation of drive-head c, effected by driving pulley e, causes the roll to swing outward against the die ring. Feed introduced through hopper f drops into the pan below the die ring and is picked up by scraper shoe g, attached to the bottom of roll b, and is thrown against the die ring, ahead of the roll. The action of the roll throws material against fixed screen h, comprising usually an inner coarse cloth protecting an outer finer cloth. Material passing the screen drops through ports i into a discharge hopper.

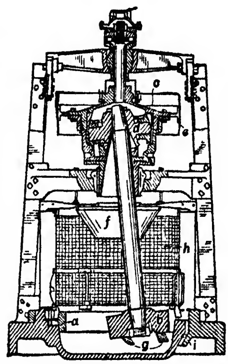

Fig. 15. Griffin mill.

Catalogue data are given in Table 4.

Performances are given in Table 18, items 34, 150.

Use. Formerly the Griffin mill was used extensively for finish grinding of cement clinker; it produces a large quantity of fines as compared with other mills of the same general type, but maintenance is high, the single-roll feature tends to cause marked vibration, and capacity is low. Present use in cement plants is limited to preliminary grinding; use for fine grinding is confined to the softer materials.

Table 4. Catalogue data on Griffin mill

Ring diam., in.	Roll diam., in.	Roll pressure, total lb.	Speed, r.p.m.	Motor, hp.	Capacity
30	16	......	220	....	....

a Limestone: 2 t.p.h. from <3/4-in. to 80% <200-m.; phosphate pebble, 2 to 3 t.p.h. to 90% <100-m.

b Limestone: 4 to 6 t.p.h. from <3/4-in. to 80 to 83% <200-m.

Bradley Hercules mill (Fig. 16) is of horizontal-roller type with screen-controlled discharge. Die ring a is mounted on the wall of a shallow tub b, the walls of which extend upward, and consist of an inner coarse and outer finer ring of screen suitably supported by uprights d and rim e. Spindle f, pinned and stuffed at the bottom into the tub casting, is surrounded by a drive tube g keyed to bevel gear h which runs in a bearing in spider i carried on cast housing j from base b. The lower end of tube g carries and drives yoke k, from which depend roll housings l supporting three rolls m. Bevel pinion n on shaft o actuates bevel gear h at 125 to 135 r.p.m., causing the 22-in. rollers to press against the 66-in. die with a pressure of about 15,000 lb. each. Feed is introduced through box p, carried on yoke k, and flows thence through three pipes q to points directly ahead of each roller. Plows on the lower ends of q also throw material from the bottom of pan b up against the die ring. The crushing action throws the contents against the screens; material passing discharges through ports r.

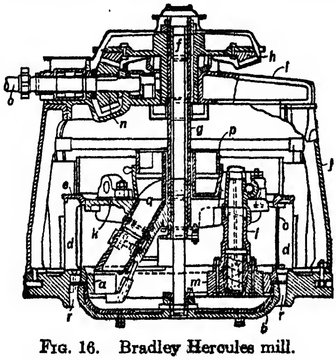

Fig. 16. Bradley Hercules mill.

Performances are given in Table 18, items 37, 48–50, 139.

Use. The mill is employed principally as a preliminary mill to grind cement rock and clinker. It is not adapted to fine grinding, since it relies upon screens for making the separation. Maintenance, particularly of screens, is high when grinding clinker and other hard and abrasive materials. Aperture of the fine screen cloth is limited as to fineness to about 20-m., although 6- to 10-m. is more economical from the standpoint of maintenance. The mill requires between 300 and 350 hp. CAPACITY grinding raw mix for cement manufacture, taking <1 1/2- or 2-in. feed, is 40 to 60 t.p.h.; grinding cement clinker it is 135 to 200 bbl. per hr., both through 6- to 10-m. screen. Feed must be dry, or screens will blind and capacity will be greatly reduced. A smaller unit, requiring about 50 to 75 hp., has a capacity of 5 to 10 t.p.h. grinding limestone for agricultural purposes (see Sec. 3, Art. 24).

The mill is sturdy, the parts are readily accessible, and screens are easily replaced, but lubrication is difficult on account of the complexity of the transmission, and bolts must be tightened frequently to prevent breakage.

Roller mills have a definite and large field in grinding soft materials and those of medium hardness and nonabrasive character to medium (the screen mills) or moderate fineness (the air-swept mills). Economic limit for the screen mill is >20-m.; the best range for the air-swept is 50 to 80% <200-m. Hard and abrasive materials cause roll faces and dies to corrugate, whereupon capacity diminishes and vibration becomes excessive. Renewals of rollers and dies requires more or less dismantling.

Capacity of roller mills varies roughly as the cube of the diameter of the die ring.

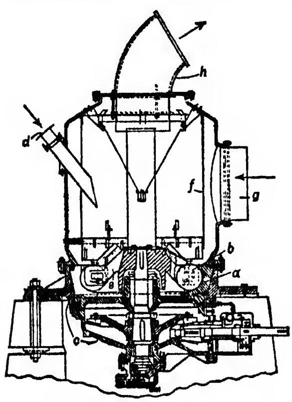

FIG. 17. Fuller pulverizer.

Ball-bearing pulverizers

These machines comprise essentially a plurality of large heavy balls rotating in conformed circular races around a central vertical axis. The races are both stationary and moving, according to the machine. Separation is made inside the housing, outside, or both.

Fuller pulverizer (Fig. 17) comprises a large concave die ring *a*, on which four large balls *b* are rotated by pushers mounted on a central vertical shaft, carried in a step in the bottom of the cylindrical frame *c*. The weight of the balls and the centrifugal force exerted by the pressure of the balls on the vertical side of the die ring creates the crushing and grinding action. The material to be ground is fed into the die ring through spout *d* from a suitable feeder; the pulverized material is raised into the classifying space within the inner housing *f* by a combination of gas blown in through *g* and forced down around *f* and through the grinding zone, and the action of fan blades carried on the pusher arms. Coarse material returns to the crushing zone along the walls of *f* by gravity; finished material is exhausted through *h* and passes thence via the exhaust fan to a cyclone or, in the case of fuel, to the firing zone. Another form essentially replaces inner housing *f* by a screen, and carries an exhauster fan in the classifying space, which fan blows material, raised from the grinding zone by the yoke fan, against the screen. Undersize drops through annular openings surrounding the grinding ring and is swept to a discharge spout. SIZES (diam. of the ring) range from 33- to 70-in.; corresponding rated CAPACITIES are from 1/2 to 15 t.p.h. grinding <1 1/4-in. soft limestone (<2% moisture in screen mills and <4% for the air-swept mills) to approximately 80% <200-m.

Performances are shown in Table 18, items 6, 28, 63, 64, 125, 128, 167, 171, 199, 219.

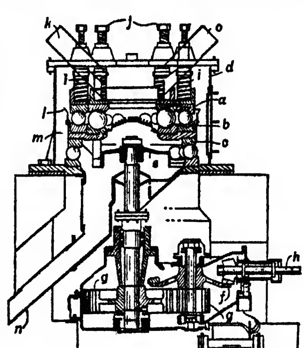

FIG. 18. B.&W. three-race mill.

B.&W. three-race mill (Fig. 18) comprises the three races *a*, *b*, *c*, each with a complement of nonconstrained balls, all enclosed in a cylindrical box *d* through which material to be ground flows in a tortuous path over the races in the order named and out of the mill without undergoing any size separation. The balls are actuated by rotation of table *e*, effected through bevel gears *f* and spur gearing *g* from a suitable driver on shaft *h*. The lower segments of races *a* and *b* and the upper segment of *c* are attached to table *e* and rotate with

it; the other races are stationary. Rotation of the movable races causes, of course, rotation of the balls. Pressure in the races is controlled in part by springs *i* and compression bolts *j*. Feed enters through spout *k* and travels successively outwardly across races *a* and *b*, and thence over crowding baffle *l*, downward through annulus *m*, and inwardly across race *c* into discharge chute *n*. Separation of finished material is made externally on a screen or classifier, and oversize is returned through spout *o*. The large balls in race *a* are 12 1/4-in., the others 9 1/4-in. Spring pressures are varied according to the material being ground; for coal, 1,500 lb. per ball is recommended. Manufacturer's data are given in Table 5.

Table 5. Catalogue data on B.&W. three-race mill *a*

366	31	43	36	680

a Grinding limestone. *b* Hardgrove grindability.

B.&W. unit mill (Fig. 19) comprises the single row of balls *A*, driven by the lower segment *B* on table *C*, which is supported on and driven by spindle *D*, actuated by bevel gearing *E*, shaft *F*, and pulley *G*. Springs *H* regulate pressure in the races. Size of discharge is regulated by the internal classifier *I*, comprising a vertical squirrel-cage fan, actuated by spindle *D*. Feed enters through hopper *K* and falls into the cone-shaped space *L* leading to the inner side of the ball race; it passes thence outwardly through the race, where it is picked up by a gas stream blown in through pipe *M*. The stream passes thence up along the walls in the annular space *N*, and thence inward through the vanes of *I* and out through pipe *O*. Coarse material in the stream is dropped out by the combined effect of decreased velocity and centrifugal swirl in the space surrounding fan *I*, and drops back into *L*, the rejection size being determined by adjusting the vanes of *I*. Outside piping varies according to requirements; see discussion of Figs. 6, 13, 14. The machine is made in 15 sizes with capacities on bituminous coal ranging from 1 to 10 t.p.h.

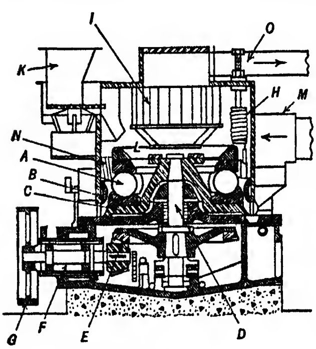

Fig. 19. B.&W. unit mill.

A two-race mill of the same general type as Fig. 18 (the lower race absent) is also made, having provision for independent regulation of spring pressures on inner and outer races. Pressures range from 1,200 lb. to 2,000 lb. per ball on the outer race, and 2,000 to 2,700 lb. on the inner. This mill is operated either air-swept or with gravity discharge; circulating loads are estimated at 500 to 1,000% for the former and 400 to 1,000% for the latter. Speed of the larger mills is about 80 r.p.m.; higher for the smaller.

Use. The ball-bearing mill is used extensively and satisfactorily for soft materials; maintenance is high with hard and abrasive material, and replacement of wearing parts is difficult because of the considerable disassembly that must be done.

Performance. See Table 18, items 29, 30, 43, 44, 62, 79, 80.

At Spokane Portland Cement Co. (*28 #7 PQ 80; 31 #1 PQ 69*) a No. 238 B.&W. mill ground 20 to 25 bbl. clinker per hr. to a specific surface of 1,850 sq. cm. per gm., drawing 240 kw. A No. 360 mill averaged 60 bbl. per hr. to 1,900 sq. cm. per gm.; the mill drew 330 kw. and the elevator and air classifier 125 kw. The same mill ground 93 bbl. per hr. to 1,300 to 1,400 sq. cm. per gm. (83 to 84% <325-m.). Life of grinding ring ranged from 2 to 3 mo. Average cost of a ring was $500 (1938), four being required. Ball cost, $965 per set.

3. TUMBLING MILLS

Mills in this category include the batch mill, ball and pebble mill, rod mill, compartment mill and other modifications of the rotating-drum principle. The basic method of grinding is by tumbling of the media induced by axial rotation of the container assembly; the paths of the media may be free fall (cataracting) or rolling (cascading) with sufficient force to pulverize the material, which is mixed with and moves with the media.

Sec. 5 discusses the general theory of operation of tumbling mills, and presents operating data on wet grinding. The basic principles in dry grinding are the same as in wet grinding, but the application and the method of operation with auxiliary apparatus are quite different.

Batch mill

The batch mill consists of a hollow rotatable container, usually cylindrical, but also conical, and occasionally cubic, spherical, or other shape; unlined or lined with close-fitting porcelain blocks, cobbed flint bricks, buhrstone blocks, or metal-plate lining. The grinding media are pebbles, porcelain balls, or metal balls, depending upon the application. Material to be ground is charged through the manhole, in quantity about 2/3 of the struck volume occupied by the grinding media, or about 1/4 of the mill volume; this quantity is sufficient to fill the voids in the tumbling charge, but not enough to cause excessive cushioning. The closed mill is run for a time predetermined to grind to specified fineness. Unloading is done by placing a grate over the manhole and turning the mill so that the product drops through it. To prevent excessive dust in discharging, a cover or hood is usually placed either around the whole mill, or around that part which includes the manhole.

Shape. Fig. 20 is typical of a small cylindrical batch mill built as a self-contained unit. The particular form pictured is equipped with a valved draw-off pipe *a* for unloading wet pulp. One bearing is normally of trunnion type *b*, which permits control of pressure during the grind, and control of the composition of the gaseous atmosphere, determination of temperature in the grinding zone, etc. Shell shapes other than cylindrical tend to cause the motion of the contained solids, both media and material, to have components parallel to the axis of rotation (Fig. 21), which, in general, minimizes segregation of the media by size, and makes for quicker and more complete mixing of materials. Shells are sometimes jacketed for temperature control, provision being made for circulation of heating or cooling fluids.

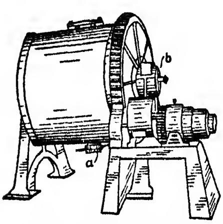

FIG. 20. Cylindrical batch mill.

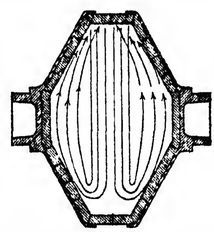

FIG. 21. Conical batch mill.

Lining. Metal lining is preferable from the standpoint of range of choice as to shape, ease of placing, and durability (see Sec. 5, Art. 5). Silex or buhrstone lasts longer and offers a rougher surface than porcelain; this decreases slip, resulting in better grinding action, but the blocks are more irregular and do not fit together as well as porcelain, so that such a liner is harder to clean. This is important if the mill is used to grind different colors, and the color is changed frequently.

Media. Crushing effect and power consumption are roughly proportionate to the specific gravity of the media. Steel balls chip less than flint or porcelain, hence consumption is less; they are smoother; because of their higher sp. gr., smaller sizes can be used for a given necessary impact, and hence more grinding surface is made available; they are normally used unless metal contamination is not permissible. Usual sizes of media chosen for different sizes of feed are given in Table 6. See also Sec. 5, Art. 6.

Imported flint pebbles, size A-1, approximately 1/2-in. diameter, average 100 pebbles to the pound; size 00, ranging from 1-in. to 1 1/2-in., average 8 to the pound; No. 3, 2 1/2-in. to 3 1/2-in., average 0.75 per pound. Porcelain balls, 1/2-in., average 133 per pound; 1 1/4-in., 10 per lb.; and 3-in., 0.9 per lb. Steel balls, 1/8-in., average 3,450 per lb., 1/2-in., 52; 1 1/4-in., 3.3; 3-in., 0.25.

Table 6. Sizes of grinding media for batch mills

Feed, mesh	Size of pebbles, in.	Size of steel balls, in.
<1/4-in.	1 1/2 to 2	1 to 1 1/2
<10-m.	1 to 1 1/2	3/4 to 1 1/4
<20-m.	3/4 to 1	5/8 to 7/8
<100-m.	1/2 to 3/4	1/2 to 5/8

Capacity is determined by the time that it takes to grind, plus charge and discharge time. Grinding time depends upon hardness of the material, moisture content, size of feed, fineness of product, size of mill, size, shape, and weight of the grinding media employed, speed, character of lining, and weight of material charge. For discussion of the effects of various factors, see Sec. 5. In general, the more power the mill can be made to draw, with charge of a given material in, the shorter the grinding time. It ranges from a few minutes for easily reduced substances and relatively coarse product to several days for material hard to reduce, and an extremely fine product.

Rate of reduction, as measured by limiting sizes, is a matter of diminishing returns. A 7×8-ft. silex-lined mill, charged with 3,000 lb. <14-m. dry feldspar and 13,000 lb. of flint pebbles drew 33 hp. After 1 hr. the product was 7% >65-m., 48% <325-m.; after 4 hr. it was 0.06% >100-m., 79% <325-m.; after 7 hr., 0.01% >140-m., 86% <325-m.

It follows that reduction rate is less than in a continuous mill, and much less than in closed-circuit grinding in a continuous mill; see Sec. 5, Fig. 9 and discussion, and Art. 12.

Catalogue data are given in Tables 7 and 8.

Performances are shown in Table 18, items 21, 56, 98, 109, 110, 161.

c After Patterson Foundry & Machine Co.

Uses. Batch mills are used for grinding colors, enamels, lacquers, ceramic materials, pigments, drugs, chemicals, minerals, and metals. The mill has largely supplanted the buhrstone mill; it is normally more efficient, has more capacity per unit of floor space, and lower power and maintenance costs. The buhrstone mill produces a more desirable particle shape in some cases. The batch mill does not require preliminary mixing of charge ingredients, as does the buhrstone. Essentially the mill is suited to intermittent grinding operations of variable character and small tonnage; or where mixing or concomitant chemical reaction is an important part of the operation.

Jar mills are small batch mills used primarily for research and test purposes, although certain products required in small amounts are ground commercially in this type of mill. The jar is usually made of vitrified porcelain or wear-resisting metal, equipped with a closely fitting cover; charge is light. The support is a cantilever shaft carrying a frame into which one or more jars is clamped, or the jar is laid on two parallel rollers, and driven by friction. Jar sizes range from 5×5- to 24×24-in. outside with charge capacities of 1 to 80 lb.

Rod mill

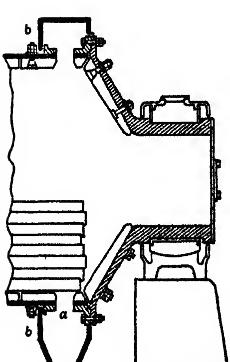

FIG. 22. Peripheral-slot discharge for rod mill.

Dry-grinding rod mill is constructed essentially like the wet-grinding rod mill, Sec. 5, Art. 7.

Discharge. Action of material undergoing reduction in dry or semidry state is much more sluggish than when mixed with enough moisture to become fluid; hence provision must be made in continuous dry grinding to move the material through the mill fast enough that proper grinding action occurs. The usual expedients are to substitute a heavy grate for the discharge-end head (*e.g.*, as Sec. 5, Fig. 55); to use an end gate that leaves an annular opening (Sec. 5, Fig. 26); or to discharge through peripheral slots *a*, Fig. 22. Hood *b* surrounds the discharge ports to confine dust.

Cone-end rod mill (as Fig. 22) permits feed to work into the rod mass over the entire vertical section of the rod load, since the rods keep in vertical alignment. This is helpful in dry grinding, because it aids in getting the feed into the load and in building up a head behind it, which is necessary owing to the sluggish nature of the dry material and its relatively high angle of repose.

Use. The field of the mill in dry grinding is limited. Its best application is in grinding hard feed of 3/4- to 1-in. limiting size, or soft feed 1 1/2- to 2-in. limiting, in open-circuit to 4- or 6-m., in making industrial sand. In such service the rod mill has the advantage of being able to grind, without packing, materials containing considerable moisture, but not enough to render the mass fluid.

The mill has been used in making sand-lime brick, where a mixture of sand and lime, with sufficient water added to make it damp, is lightly ground and mixed. The rods break down the coarse sand and do a thorough job of mixing and coating the sand particles with the lime.

Rod mills have been operated in closed-circuit with air classifiers and screens, but if a product finer than 10-m. is wanted, better results can be secured in a ball mill.

The mill has been used to grind coke, as for carbon electrodes; it makes a uniform product of desirable shape characteristics; it is operated open-circuit, or closed-circuit with a screen.

Table 9. Catalogue data for dry-grinding rod mills (*after Hardinge Co.*)

a Average rock.

The rod mill is not necessarily a better granulator than a ball mill, if the latter is operated closed-circuit with a proper classifying device. However, in open-circuit, when no tramp oversize is permissible, the rod mill is supreme in the tumbling-mill field, as it does not overgrind while keeping coarser sizes within the required range. It cannot handle high circulating loads.

Catalogue data are given in Table 9.

Performances are given in Table 18, items 85, 86, 88, 102.

Ball mill

The ball mill is most widely used of all types of pulverizers. It is simple and rugged in construction, not difficult to operate reasonably well, and maintenance against wear in grinding requires less delay and labor than in any competing machines. For pulverizing soft nonabrasive materials, however, the fixed-path mills (Art. 2) consume less power, and with maintenance a minor factor, they have the advantage. The ball mill is not directly applicable in dry grinding, if there is enough moisture in the feed to induce coating of balls or packing of charge. Drying must be resorted to in such a case. Dry discharge, from predried feed or resulting from in-mill drying, is necessary in operations with classifiers. Hence for hard and abrasive materials and products finer than 10-m., the ball mill qualifies on the ground of a maintenance cost low enough to overcome its handicap in power consumption; for fine grinding it is pre-eminent in the hard-material field, and worthy of serious consideration for soft materials.

Action in dry-grinding ball mills. The general principle of operation of dry-grinding ball mills is similar to that of wet mills (Sec. 5, Art. 2), but there are several important differences, *viz.*, flow characteristics, cushioning effect, ball-coating tendency, and response to a small quantity of moisture.

Flow. Dry material is definitely resistant to flow, owing to its great internal friction. This results in a large angle of repose, which requires either a steep gradient for gravity flow or a high pressure head in order to move material into and through a tumbling mill. A steep gradient is obtained in the

mill by increasing the diameter-length ratio of the shell, and by some form of peripheral discharge (see *Rod mill*). Air sweeping has somewhat the effect of an elevator at the discharge end to lift material into the discharge trunnion (but it has the correlative effect of removing the fine material that tends to lubricate the load, and thus increase resistance to flow. *Ed.*). See also *Krupp mill*. It is much easier to overload a dry mill than a wet one. A steep gradient into the mill is obtainable only by using a large or a short feed trunnion; the former robs the mill gradient; the latter requires a special bearing. Hence some form of positive feeder, *e.g.*, a screw conveyor, is ordinarily used, with a small trunnion to aid mill gradient.

Cushioning is the reaction of a mass of comminuted solids to an impact; it consists in a readjustment of the mass in such a way as to distribute the energy over the large interfacial contact surface within the mass and to dissipate it in friction and local fine pulverization, without any breakage commensurate with the energy expended. It is a serious hindrance to effective fine grinding in any type of mill, but tumbling mills are particularly subject to its ill effects. The remedy is to reduce the interstitial load to a minimum consistent with the requirement of always maintaining some material between contacting grinding surfaces. From a practical standpoint this means flowing tonnage through the tumbling charge as rapidly as is possible without building up circulating load to such an extent that the interstitial space becomes overcrowded and the excess rides the surface of the tumbling charge. Air-sweeping is of benefit here, since it removes much of the fine material as and at the point in its travel through the mill at which it is formed, thus taking out of the interstitial load both volume and impact-absorbing surface.

Ball coating means the formation of hard, coherent layers of compacted fine feed material on the surface of the grinding media. It is not a moisture effect in the ordinary sense, since it happens readily in dusty material. The cause is unknown. The effect is to substitute a relatively soft grinding surface for the original hard one, and thus decrease grinding effect markedly (see Sec. 5, Art. 6). One remedy, effective with some materials, notably cement clinker, is to introduce a fatty material, or a hydrocarbon containing an acidic ingredient, in small quantity with the feed (see Sec. 3A, Art. 5). Air-sweeping a mill usually eliminates the tendency to ball coating.

Speed; ball charge; power consumption. Owing to the high internal friction of the dry interstitial material, ball charges carry higher on the upcoming side of a dry ball mill than in a wet mill. As a result dry mills are operated at lower peripheral SPEEDS than wet, usually about 10%. BALL LOADS must be smaller in the dry mill (35 to 45% of mill volume) to prevent cataracting, with consequent hammering of the breast of the mill and loss of fine-grinding capacity. BALL R TIONING (Sec. 5, Art. 6) is equally important in both mills. POWER CONSUMPTION, on the other hand, is about the same for shells of the same sizes wet and dry, although it is higher per unit weight of tumbling charge in the dry mill, despite the reduction in speed, and is from 10 to 20% higher per unit of a given fine material produced in a mill operating properly. If a trunnion-discharge mill is run without means to aid throughput, power consumption per ton ground to a given mesh may run 50 to 65% above that in wet milling.

Length of shell. Early practice in fine dry grinding was to use a large length-diameter ratio. This was wasteful of power, but was necessary if a small limiting size of product was imperative, because there was no effective means of separating finished from unfinished material during the operation. Compartmentation of the shell, with rationing of the ball load to the duty in successive compartments, was the first approach to a cure. Modern air classifiers would seem to be, if not a better one, a valuable auxiliary, and modern practice is recognizing the fact (see Sec. 3A, Art. 7; Sec. 9, Art. 11). If ultrafineness is necessary, a long compartmented mill is probably the better installation, at least for the finishing grind.

Dry *vs.* wet grinding. POWER CONSUMPTION in wet grinding is 60 to 90% that in dry. BALL and LINER CONSUMPTION in dry work is 10 to 25% that in wet, and wear on the auxiliary apparatus is also less, not improbably owing to less oxidation in the dry circuit, and less metal-to-metal contact. CAPACITY of a dry mill per unit of mill volume and /or per unit weight of tumbling charge is less than in wet work. The balance between the resultant COST differences is close enough for the choice between the wet and dry methods to swing on the efficiency of the auxiliary and subsequent operations. For a number of years mechanical wet classifiers were enough more efficient than dry and wet blending more accurate and convenient to swing the large majority of cement plants to wet grinding of raw mix, despite that the water added had to be evaporated in the kiln; now (1943) both dry classification and dry blending are so improved, and air sweeping has so increased moisture tolerances, that the balance has swung in favor of dry work in several cases. In general, today, wet grinding is adopted, if the following process is wet, otherwise dry. The wet plant is easier to keep clean, but the dry can be kept as clean as or cleaner than the wet. Dry grinding is more flexible than wet, which is an advantage when products of different characteristics are to be taken successively from the same circuit.

Short *vs.* long mills. The short tumbling mill or a fixed-path mill is ordinarily used for the first stage in multistage dry work for products not finer than, say, 20- or 30-*mog*. There is a decided trend in finishing grinds of fine feeds to use short tumbling mills with classifiers, although the great majority of existing installations for such service are long mills. Short mills are structurally the grate-type wet mills (Sec. 5, Art. 10) modified as to feeding arrangement, or arranged for peripheral-slot discharge; or open-end Conical mills. Capacity of mills used for both wet and dry work is rated by manufacturers generally at 60 to 90% of wet-mill ratings.

Preliminator (Fig. 23) is a short ball mill, commonly used in dry service, characterized by peripheral-slot discharge, the two-diameter shell *b*, the large-diameter short feed-end trunnion, and chute feed. The effects of the reduced diameter at the discharge end are (*a*) to keep the larger balls at the feed end and (*b*) to reduce power consumption by reduction in ball load and torque in the part of the mill where high in-load pressures and free-fall impacts are unnecessary. Estimating data for clinker grinding, furnished by Allis-Chalmers Co., are given in Table 10.

Performances of cylindrical ball mills are given in Table 18, items 78, 114, 115, 130, 135, 217.

9 1/2×10	73,000	235	500

a Feed, <1-in. clinker of average hardness; reduced to 95% <20-m. in closed circuit. Barrel = 376 lb.

Screen-discharge ball mill

Krupp ball mill (Fig. 24) was the first of this type. Many Krupp mills are still in operation, mainly in cement plants. Newer plants are being equipped principally with other types, unless special conditions peculiarly adapted to this type prevail. The mill was never used to any great extent in metallurgical milling, the exceptions being for dry grinding prior to roasting and in crushing ores containing coarse metallics for sampling. In the latter service, metallic particles too coarse for accurate sampling are retained, and can be weighed, melted down, and bullion-sampled.

The inner shell containing the grinding media is built up of hard-iron or alloy-steel wearing plates *a*, containing coarse perforations as shown. These plates are bolted between heavy cast heads which are, in turn, fastened to a heavy through shaft. One end of the shaft carries a large gear, driven by means of the pinion and pulley shown. Surrounding the perforated plates *a* are circumferential sections of punched-plate screen *b*, with relatively coarse aperture, and surrounding this a ring of fine screens *c*. Both sets of screens are bolted to the heads and revolve with them.

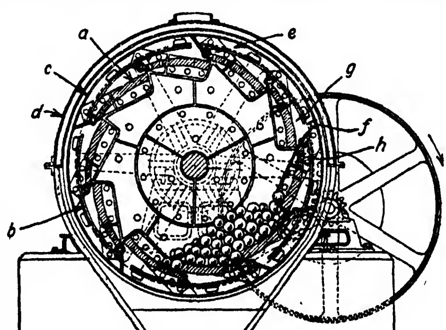

FIG. 24. Krupp ball mill.

The revolving part is all contained in a sheet-iron housing *d*, having a hopper bottom for discharge of screened material. In operation, feed is introduced at one end of the cylinder, at the center around the shaft. When sufficiently ground by the balls to pass the large apertures in the grinding plates *a*, the material falls through to screen *b*. That part of the ground material that will pass the relatively coarse meshes in screen *b* does so,

and is subjected to screening by the fine screens *c*. The material that passes through these fine screens discharges from the hopper finished. That material which will not pass through screen *c* is carried around in the space between *b* and *c*, to the position marked *e*, when it falls through opening *f*, into chamber *g*, and joins material that passed the heavy liner plates but would not pass *b*. From chamber *g* both materials pass through an opening at *h*, back into the crushing chamber, and are there again subjected to crushing action by the balls. Table 11 gives data on commercial sizes of this machine as furnished by one manufacturer. The balls used are the same as those in other ball mills.

Table 11. Sizes and weights of Krupp ball mills
(*Catalogue data*)

Size numbers	Weight without charge, lb.	Weight of balls, lb.	Capacity on cement clinker to 20-m. bbl. per hr. *b*	Horsepower required *a*
7	29,500	3,000	12 to 16	30 to 40
8	41,100	4,500	18 to 24	40 to 50

a From 100 to 120% additional power is required momentarily in starting.

b When pulverizing to pass 20-m., from 30 to 40% will pass 100-m.

Performances are given in Table 18, items 39, 40, 51. The mill has the advantage of being able to take a wider range of feed sizes than the ordinary ball mill. The product is relatively uniform and devoid of superfines. Typical screen analyses for clinker grinding are:

Screen:	1-in.	3/4	1/2	3/8	1/4	8-m.	16	30	50	100	200	<last.
Feed, %	1.7	1.2	5.0	5.2	23.2	32.5	21.1	6.8	....	...	....	3.3
Product, %....	...	...	...	....	5.5	30.5	17.5	14.0	7.5	11.0	14.0	

Unless the feed is quite dry, screens clog quickly. Screen wear is localized and high, and screens break frequently. Cleaning and repairing screens requires stoppage, and removal of the hood. Fineness of product is substantially unaffected by change in feed rate; to effect such change requires screen change. Ball and liner consumption are heavier than for screenless mills.

Smidth Kominuter (Fig. 25), like the Krupp mill, consists of a generally cylindrical revolving stepped grinding shell *a* within a revolving compound guard screen *b*, rotating

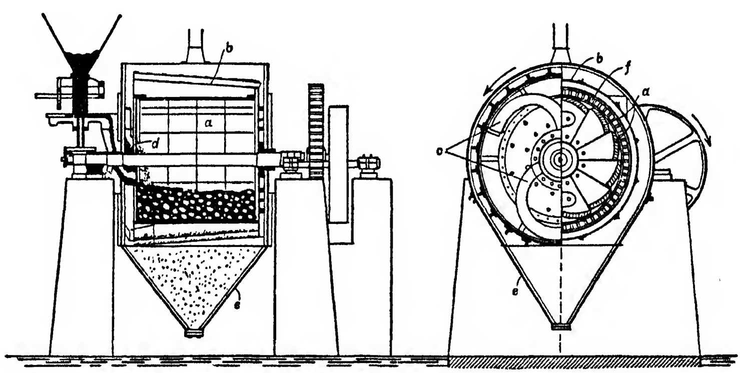

FIG. 25. Smidth Kominuter.

with the shell, and flared toward the feed end to transport oversize to the spiral-pipe elevators *c*, which return it to the feed inlet *d*. Undersize of the outer finer screen falls into discharge hopper *e*. Unlike the Krupp mill, material being ground must pass from one end of the mill to the other where it discharges through a peripheral grate *f*. This makes it possible to regulate fineness to some extent by a change in feed rate. The mill is sensitive to overloading. SPEED must be kept below cataracting to prevent the balls from striking the central shaft. FEED must be dry or be dried during grinding (see Art. 2). Maintenance requires considerable dismantling, and is relatively frequent because it involves screen replacements. CAPACITY and POWER CONSUMPTION are about the same as for the Krupp mill.

Performances are given in Table 18, items 41, 42.

The Kominuter is somewhat more flexible in operation, and makes a finer product than the Krupp mill, but is more difficult to repair.

Ball-tube mill

Ball-tube mill is a long cylinder (length ordinarily two or more times diameter) with generally plane or conical ends, usually trunnion-supported, with trunnion feed and discharge. It may or may not have a grate at the discharge end. Grinding media are steel or cast-iron balls, punchings, or specially shaped castings, the size depending upon the size of feed; usual maximum size of charge for 10-m. feed is 1 1/2-in. diameter, about 3/4-in. for 20-m. or finer. Feed size is normally less than 1/8-in. limiting, unless the mill is compartmented. Grates, if used, are ordinarily of lifter type (Sec. 5, Figs. 45, 47, 54, 57).

Use of tube mills for dry grinding is dependent upon the fact that most finely powdered dry material while undergoing agitation in the presence of a gas becomes sufficiently dilated to acquire semifluid character, so that flow can be maintained even with the low gradient possible in a long mill.

Argument on the use of classifiers in dry grinding in long mills still continues after many years of experience with the mill. Early practice in clinker grinding, where it is almost universally used for finishing, was to run open-circuit. Thus run, most (70 to 90%) of the reduction to limiting product size is done in the first quarter of the length. This means that three-quarters of the energy input is expended, so far as limiting size specifications are concerned, in grinding 10 to 30% of the feed. Under such an analysis, there is no question but that closed-circuiting with a classifier is indicated. On the other hand, the mill does a great deal of production of surface while reducing this 10 to 30% oversize to the specified limiting size, and when the product specification also includes a high surface minimum, the necessary classifier and elevating equipment becomes extensive, and expensive both to instal and operate. The modern trend in clinker grinding appears, however, to be toward classifier circuits and shorter mills except when superfine cements are being made (Sec. 3A, Art. 7). When classifiers are used, mills are normally grated in order to increase throughput; the result is, ordinarily, to increase steel consumption, because of the light interstitial filling in the tumbling load near the grate. When a so-called plastic (smooth-textured) product is wanted, the mill is run open-circuit.

Feed rate must be uniform. There is a definite tendency for mill discharge to surge and become unduly coarse at the surges, even with constant feed; such surging is aggravated with fluctuating feed rate.

Catalogue data. The data in Table 12 are based on actual operation for one or more mills of different sizes grinding the particular materials through the ranges shown, and interpolations for the other sizes. The larger mills grind somewhat more efficiently than the smaller, but this is not nearly so apparent as with the short ball mill.

Performances are given in Table 12, and in Table 18, items 19, 31, 53, 54, 91, 123, 194, 195.

Table 12. Performances of grate-type ball-tube mills in dry grinding (*after Hardinge Co.*)

Size, diam. × length, ft.	Maximum ball load, lb.	Motor, hp.	Normal r.p.m.	Cement clinker from 97% <200-m. to 95% <325-m., bbl. per hr. *a*	Limestone from <12-m. to 95% <100-m., t.p.h. *b*	Calcined gypsum to 95% <100-m., t.p.h. *c*

a Closed-circuit with air classifier. Product size is equivalent to 1,750 to 1,800 sq. cm. per gm. specific surface. Clinker of average hardness. Barrel weight, 376 lb.

b Open-circuit; moisture less than 1/2%; average grindability.

c Feed temperature, 200° to 300° F. Object, to increase plasticity. Open-circuit operation.

Compartment mill

Compartment mill (Fig. 26) is a combination in one shell of a short-cylinder preliminary mill and a ball-tube mill. The mill has two, three, or four compartments, depending upon the size of feed and the product wanted. The entire shell may be a single cylinder or the feed end may be made of greater diameter than the balance (see description of *Preliminator*, p. 16).

In the particular mill shown in Fig. 26 the cylindrical part of the shell *s* in the first compartment is 9 1/2-ft. diameter, the shell of the balance of the mill is 8-ft. diameter and compartment lengths are 10-ft The mill may be trunnion-supported, as shown, or have

tire-and-roller support. Diaphragms are of several forms. That shown in Fig. 26, and in more detail in Fig. 27, comprises a grate *a*, discharging into annular chamber *b* and thence out of the mill shell proper, through circumferential ports *c* into an annular chamber *i* between the mill shell and a peripheral screen *d*, attached to the mill, and rotating

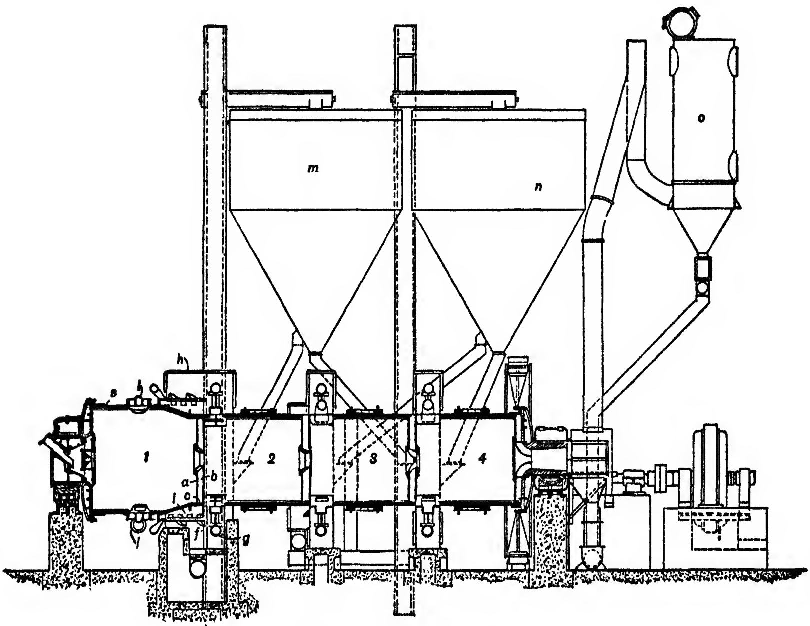

FIG. 26. Compartment mill.

with it. Screen oversize is moved by spirals *j* into the small sump *k* from which it is picked up by two spiral pipes *e*, spaced around the shell 180° apart, which return it into the first compartment at the manholes *l*. Undersize falls into a sump *f* and is picked up by scoops *g*, which elevate it to the second compartment. This entire diaphragm arrangement is enclosed in a dust-tight housing *h* which is connected to a dust collector; a negative pressure is maintained therein to prevent dusting. In Fig. 26 the first compartment is shown in closed circuit with the mill screen, as described; compartments 2 and 3 are in closed

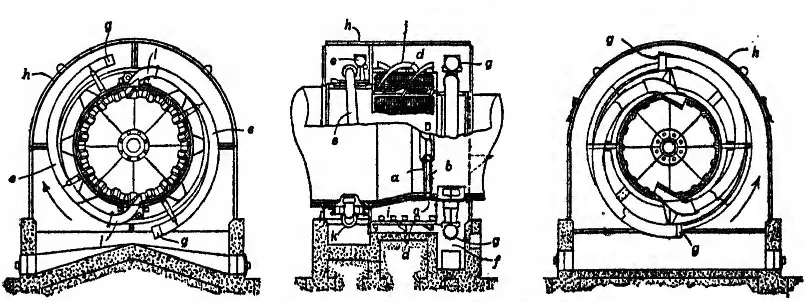

FIG. 27. Diaphragm for compartment mill (Fig. 26).

circuit with air classifiers *m* and *n*, apparently parallel-fed, which return undersize to the respective compartments, but which by-pass undersize of compartment 2 to compartment 4; compartment 4 is in open circuit; dust collector *o* guards its discharge.

Fig. 28 shows the grid-type division head. The grinding compartment is open into the squirrel cage *a*, made of tool-steel bars, which retains oversize. Undersize passes into annular chamber *b*, and is transferred by helix *d* into chamber *c*, wherein it is lifted above

the axis of the mill by flights *e* and is spilled onto fluted cone *f* and thence into the adjoining compartment. The DISADVANTAGE of this arrangement is the pounding to which the grid is subjected by the balls; this is accentuated by removal of the interstitial load by the grid.

Tricone compartment mill (Fig. 29) comprises a primary section designed to accomplish in one compartment the results of 2 or 3 cylindrical compartments, by taking advantage of the action of a conical shell in segregating balls as indicated in the sketch. The second compartment is a safety to compensate for loss of segregation in compartment 1, which occurs when the mill is overfed. The division head consists of the imperforate conical ring *a*, flat grate *b* with a central hole, a conical-plane imperforate reflection *g* of these, a divider plate *e* surrounding a two-way fluted cone *c*, and radial screens *f* spaced around the periphery. Material from the bottom of the load at the discharge end is led by lifter fins on *a* to grate *b*. Undersize of the grate falls onto *f*, undersize of which is deflected to the discharge-end side of plate *e* and thence, via *c*, into the second compartment; oversize is deflected onto the feed-end side of *e* and thence back into the mill at *d*. The second compartment may be air-swept (Figs. 33, 34). The mill may be made one-compartment and operated air-swept, or air-sweeping may be substituted for screening in the division head.

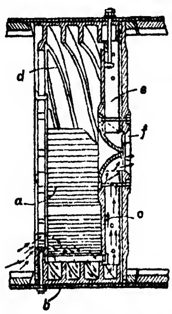

FIG. 28. Grid-type division head for compartment mill.

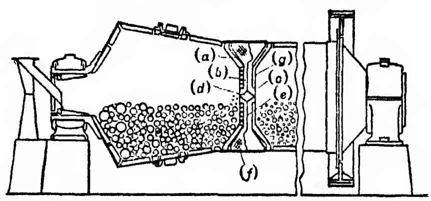

FIG. 29. Tricone compartment mill.

When sizing between compartments is not desired, a simple form of division head (*e.g.*, Fig. 30) is used. It comprises the slightly conical perforate discharge-end head *a*, a reversely coned imperforate feed-end head *b*, lifters *c* spaced around the shell in the interhead space, and a ribbed cone *d*, to lead material into the next compartment, as indicated. The discharge end of the mill is arranged similarly, with conical grate *e*, lifters *f*, and fluted cone *g*. The function of the division heads here is simply to supply gradient, and to enable ball rationing when the entire grind is done in one unit. Ball sizes in such a mill, with clinker of 1 1/2- or 2-in. limiting size, would be, say, 5~3-in. in compartment 1, <1 1/2-in. in compartment 2, and <3/4-in. in compartment 3.

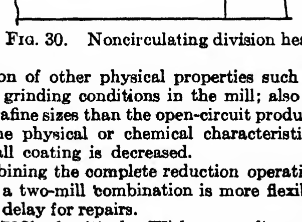

FIG. 30. Noncirculating division head.

Use. Until recently, compartment mills were run open-circuit. It has been found, however, that even in grinding cement clinker, in which service the mill has been most used, external classification improves efficiency, *i.e.*, a finer product is secured at a given capacity, or greater capacity is possible to a given fineness.

Broadly speaking, closed-circuit grinding increases capacity of a given compartment mill from 15 to 25%; more in certain cases in which a limiting size is specified without specification of other physical properties such as specific surface. The improvement is due, in part, to better grinding conditions in the mill; also to the fact that the classifier product, although containing less ultrafine sizes than the open-circuit product, could be substituted for it without detrimental effect on the physical or chemical characteristics. Mill temperature is lower in closed-circuit operation, and ball coating is decreased.

Originally the compartment mill had the advantage of combining the complete reduction operation in one unit. If, however, closed-circuit grinding is practiced, a two-mill combination is more flexible and can be run efficiently at lower operating cost and with less delay for repairs.

Speed of compartment mills ranges ordinarily from 72 to 78% of critical. With a two-diameter mill speed is a compromise.

Moisture should not exceed 1/2 to 1% by weight; higher moisture content reduces capacity appreciably. If initial moisture s higher than 1%, a separate drier should be used, or heated air passed through the mill. With dry feed, the heat generated in grinding may raise mill temperature to such an extent as to alter the character of product. In grinding cement clinker, water is frequently sprayed on the mill shell to keep temperature down. Closed-circuit grinding with air classifiers reduces temperature considerably.

Lubrication is difficult, owing to the excessive weight of large compartment mills and the relatively high temperatures at which they operate. Special bearings are offered by different manufacturers, *e.g.*, (*a*) internal pick-up buckets (Allis-Chalmers), or (*b*) disc-and-wiper (Hardinge), both of which raise oil from a sump and direct it over the trunnion bearings; (*c*) forced lubrication; (*d*) Smidth saddle bearing (*41 #5 RP 41; 144 #10 J 81*), shown in Fig. 31, which is a substitute for the ordinary roller supporting the tire, and comprises two slide shoes with ball and socket joints, placed unsymmetrically with respect to the resultant load, all enclosed in a dust-tight covering. Unit pressures vary along the length of the shoe. This permits the oil film supplied to the tire by dip lubrication and adhering thereto to enter the space between the tire and slide shoe. It is estimated that the oil film thus maintained is from 0.005 to 0.010 in. thick. A further advantage claimed is that inaccuracies in tire shape, diameter, and location are automatically compensated for by slight movement of the shoe, and that the bearing is self-adjusting to expansion and contraction due to heat.

Table 13. Catalogue data for compartment mills grinding cement clinker (*after Allis-Chalmers Mfg. Co.*)

Size, diam. × length, ft.	Weight of ball charge, lb.	Estimated capacity, bbl. per hr. *a*	Nominal motor hp. (mill only)
5×22	45,000	23	200
6×22	64,000	36	300
7×26	102,000	67	500
8 & 7×32	142,000	94	700
9 1/2 & 8×35	195,000	135	1,000

a <1-in. clinker of average hardness reduced to specific surface of 1,800 sq. cm. per gm., or approximately 96% <325-m., in closed-circuit with an air classifier.

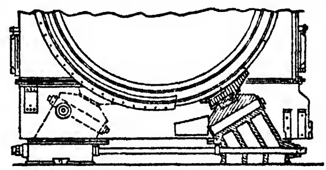

FIG. 31. Smidth saddle bearing.

Catalogue data for a few sizes of compartment mills grinding cement clinker in closed-circuit are given in Table 13. Capacities vary considerably with the hardness of the clinker and its size. The power figures do not include power for elevator, screw conveyor, and air classifiers, which amount to an additional 15 to 25%.

Performances are shown in Table 18, items 32, 33, 127, 164, 175. See also Sec. 3A, Art. 7.

Conical ball mill

General construction is the same as that of the wet-grinding mill (Sec. 5, Art. 9), modified for adaptation to dry-grinding conditions. Thus the heaping of load which occurs in the cylindrical section, taken with a short feed-end trunnion, permits gravity feed through a chute feeder (Fig. 32), except in unusual cases. Discharge is by various means. The simplest is as in wet grinding, *i.e.*, an open trunnion with a ball-retaining grate, used for free-flowing material. Usually the grate is placed part way down the cone, and a fluted discharge nose *a* lifts material into the discharge bell.

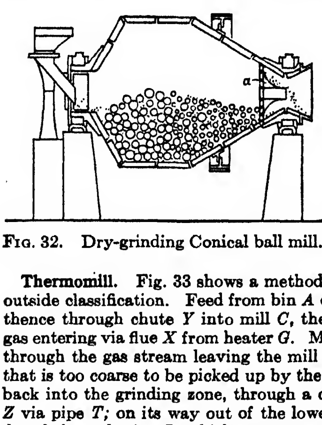

FIG. 32. Dry-grinding Conical ball mill.

If the mill is arranged for operation with an air classifier, short radial lifters are placed just outside the grate to shower grate undersize across the air stream leaving the mill (see item *V*, Fig. 33).

Thermomill. Fig. 33 shows a method of sweeping the Conical mill with hot gas, in connection with outside classification. Feed from bin *A* discharges via feeder *B* into an air-locked hopper *Z*, and passes thence through chute *Y* into mill *C*, the weight of the feed opening the air lock into the path of hot gas entering via flue *X* from heater *G*. Material passing grate *W* is picked up by lifters *V* and is dropped through the gas stream leaving the mill and entering pipe *U*, which delivers to classifier *D*. Material that is too coarse to be picked up by the air stream is picked up by one special lifter which discharges back into the grinding zone, through a central opening in the grate *W*. Classifier oversize returns to *Z* via pipe *T*; on its way out of the lower portion of classifier *D* it passes countercurrent to gas introduced through pipe *L*, which scavenges fines. Classifier fines pass through pipe *R* to collector *E*, and are discharged through an air lock into bin *J*. Fan *F* takes suction on *E* through *S* and blows clean gas back into the mill. A relatively high vacuum is maintained in the system so that hot gas flows readily into the feed end of the mill. Moisture-laden gas is bled off at a rate necessary to maintain the desired humidity in the mill by venting direct to atmosphere through stack *Q*, or through auxiliary fine-product collectors. It is common practice to operate this system on coal containing as much as 12 or 15% moisture, and on materials of higher specific gravity containing up to 8 or 10% moisture, varying air temperatures according to moisture content. Automatic temperature and capacity-control devices are employed. Entering air temperature may be 1,000° F. or more without raising exit temperature above 140° to 160°. Electric Ear sound control of feed rate (Sec. 5, Art. 18) is an important adjunct to such a system. Separations have been made over the range from <10-m. to 99.9% <325-m., but screens

are ordinarily better for coarse separations. A separate drier is preferable for very wet feeds where no adequate means are available to separate moisture-laden gas from the fines.

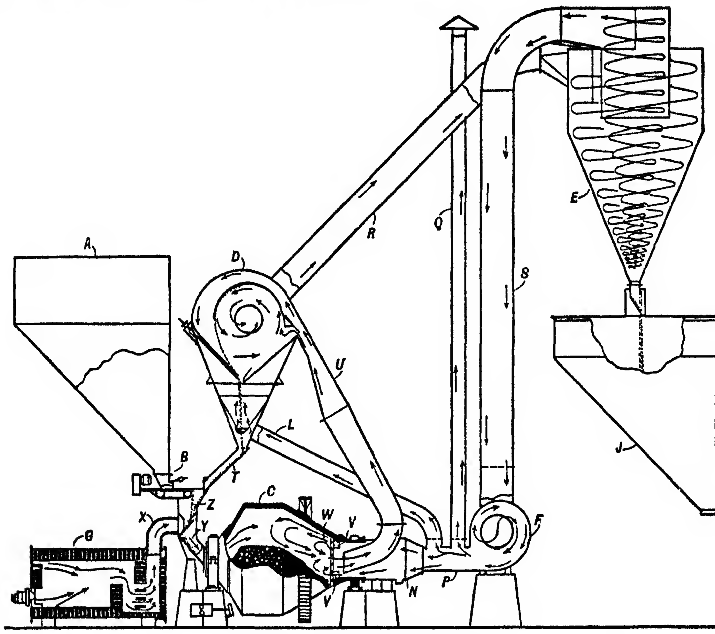

Fig. 33. Hardinge Thermomill.

Unit mill for preparing powdered fuel routes R (Fig. 33) to the burner, eliminates G, and blower F takes suction through S on kiln, cooler, or the like. Without recuperation, pipe P is cut off at N, eliminating pipe L and its function, and atmospheric air enters at N, in quantities controlled by a suitable damper, because of suction engendered by the classifier fan.

The unit ball-mill system requires somewhat more power and floor space than modern high-speed fixed-path pulverizers, but is superior for abrasive coals.

Another arrangement of a ball mill as a unit mill is shown in Fig. 34. The grinding unit a is a Tricone mill. Preheated gas enters through duct b and sweeps directly through the mill countercurrent to the flow, thence out through the large feed trunnion into a classifying chamber c (see Sec. 9, Art. 11) which drops coarse material back into spiral feeder d, while powdered coal passes up through suction pipe e of exhauster f and thence to the burner. Feed enters at g. An insulated housing h surrounds the mill. Bearings are water-cooled. Suitable dampers regulate gas flow. The mill has large trunnion openings, so as to reduce the pressure differential required to flow gas through the system; this is particularly necessary where high temperatures are not available for drying, as when hot air is obtained from indirect heating chambers around furnace walls and the like. Wet feed mingles with dry oversize, so that surface moisture is largely evaporated by the time the feed enters the grinding zone. Damper i controls the capacity; when it is opened, the volume of gas passing through the mill is reduced, decreasing the amount of coal removed, but since outside air enters the fan through the damper, the velocity of the air in the burner pipe is maintained, which keeps coal in suspension.

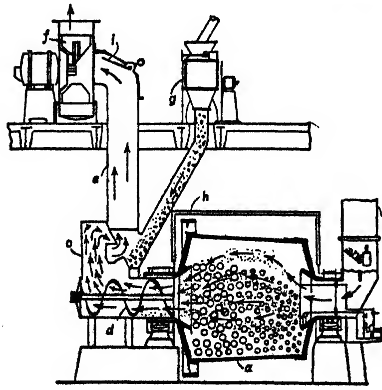

Fig. 34. Tricone unit mill.

Catalogue data for Conical ball mills grinding dry are given in Table 14. Actual capacities may vary considerably from those indicated, depending upon conditions of operation and hardness of material. **Performances are given in Table 18.**

a Closed-circuit with vibrating screen; product will contain 38 to 42% <200-m.
b Closed-circuit with Hardinge air classifier; fan power about 4 to 5 hp. per ton. Hot air used when moisture exceeds 2%.
c Closed-circuit with vibrating screen; product will contain 35 to 40% <200-m.
d Closed-circuit with Hardinge air classifier; fan power 2 to 2.5 hp. per bbl.
e Mill either as unit pulverizer for direct firing or sending air-classifier product to hot storage; air used if moisture exceeds 4%.
f Closed-circuit with Hardinge reversed-current air classifier; fan requires about 7 hp. per ton.
g Assumed as river coal with 10% to 25% sand; very hard grinding; 6 hp. per ton additional air-classifier fan power.
h Average (South Africa) chrome ore pre-dried; crushes readily but hard to grind; add 6 hp. per ton for air-classifier fan power.
i Concentrated ilmenite from beach sand (India); very hard. Closed-circuit with Hardinge air classifier requiring 9 hp. per ton additional.
j Bbl. per hr.
k Medium hardness.

Pebble mills

The principle of operation of a dry-grinding pebble mill is substantially the same as that of the ball mill. The only essential difference between ball and pebble mills is the grinding medium, and, usually, the lining. Within the useful range of operation, tons per hp-hr. from a pebble mill is, in many cases, equal to ball mill performance. The pebble mill cannot, however, handle as coarse feeds as the ball mill. A pebble-tube mill is practically limited to <8-m. feed, if the material is at all hard; better results are secured with even finer feeds. Conical pebble mills can take up to <1/2-in. feed. Pebble-mill circuits are like those described for ball mills. Grinding media are as for wet pebble mills (Sec. 5, Art. 6). Floor space required is greater than that for the equivalent ball mill, since capacity is roughly proportionate to weight of tumbling charge.

Table 15. Catalogue data for pebble-tube mill; dry grinding (*after Hardinge Co.*)

a Medium-hard limestone; closed-circuit with Hardinge air classifier consuming approximately 3 hp. per ton additional power.
b 60-m. trunnion trommel; small amount of oversize returned to feed end by hand.
c Closed-circuit with vibrating screen; 12 to 15% <200-m.
d Closed-circuit with Hardinge air classifier consuming approximately 15 hp. per ton.
e Used as filler or in special ceramic ware. Air classifier requires about 20 hp. per ton of product.

Use. Substantially the only use of the pebble mill today (1943) is when prevention of contamination is the prevailing consideration.

Catalogue data for pebble-tube mills and Conical pebble mills are given in Tables 15 and 16.

Performance data are given in Table 17. In Table 18, performances of Conical pebble mills are items 4, 11, 22, 25, 55, 95–97, 99, 100, 108, 111, 151, 162, 189, 191, 197, 198, 207, 211; cylindrical pebble mills, 95; pebble-tube mills, 52, 145, 186, 190, 208.

Cascade mill

Cascade mill (Hardinge Co.) is a tumbling mill with diameter 2 1/2 to 3 times its cylindrical length, fitted with obtuse conical ends, gear-driven in the usual fashion. It is designed to operate using the crude itself as the grinding medium. Its use depends upon the presence in the run-of-mine or quarry product of sufficient material, in lumps at least 5-in. and up to 10-in. size, tough enough not to crack up in tumbling and hard enough to grind the natural grains of the ore, to supply impact and interparticle nip (Sec. 5, Art. 2).

ch Detailed performance data for dry grinding are scarce and hard to collect. The data given in this table were collected over a period of many years by the staff of the Hardinge Co., the sources being, except where otherwise footnoted, operating observations by staff members, or private communications from operators. The predominance of data concerning Conical mills is not to be taken as a representation of similar predominance in installation frequency; it results from the fact that these were naturally the items of maximum interest to the collectors of the data.

Crude is sized at 2- to 4-in., according to the amount of coarse material present, and oversize and undersize are separately binned. Feed to the mill is then drawn from the coarse and fine bins in such proportions as to maintain suitable quantities of lump material in the mill. The mill is swept with hot air. The manufacturer offers mills 5- to 20-ft. diameter, powered at 6 to 1,200 hp. CAPACITIES are rated at about 1 ton per hp.-day to 70 to 80% <200-m.

At CONSOLIDATED MINING & SMELTING Co. a 12×4-ft. mill ground 140 t.p.d. of regular run-of-mine ore to 84% <200-m. with a total power consumption, including feeding, grinding, and air classifying, of 18 kw-hr. per ton. The ore was quartz and schist; after grinding, it was pulped and cyanided. Electric Ear sound control units added to two of these mills increased over-all capacity 15% (C. T. Oughtred, *PC*).

4. OPERATION OF DRY-GRINDING MACHINES

The gauges of operation, with the product specified, are capacity and cost. Each of these, in dry grinding, depends upon a variety of factors having to do with (*a*) the raw material, (*b*) the product specified, (*c*) the machine used, (*d*) the auxiliaries, and (*e*) the way in which both machine and auxiliaries are run.

Raw material is, to a much greater extent than in wet operation, the controlling factor in the choice of a mill for dry grinding. For this reason Table 18, giving capacities and power consumptions of a variety of mills in a large variety of services, is arranged in alphabetical order of materials ground.

Raw materials vary widely in native characteristics and in the state in which they come to the grinding plant. The important criteria are innate resistance to grinding forces, size, and moisture content.

Grindability is broadly defined as the response of a material to grinding effort. As of the present, a variety of methods aimed at numerical expression of grindability have been proposed (Sec. 19, Art. 11). The Hardgrove method is extensively used in dry grinding. Hardgrove ratings for a number of raw materials are given in Table 19. Ratings based on dry ball milling are given in Sec. 5, Table 46, and based on dry rod milling, in Sec. 5, Table 47. See also Sec. 5, Tables 44, 45, 48, 49, and the accompanying text. No method of rating has proven worthy of acceptance as standard. The ratings in Table 19 herein, having been made in a ball-bearing type of mill, are an index of probable relative behaviors of the materials tested, if ground commercially in mills of the same type. The ratings in Tables 46 and 47, Sec. 5, are of similar worth for tumbling mills. Commercial performance data are better than either, if reliable, and reasonably parallel. But the variations in rating of materials with the same chemical designation, as shown in the tables; the differences that are met with in the responses of materials from the same mine or quarry; and the differences in comparative positions of given materials in different tables, and of the same material ground to different sizes as listed in the same table, are all their own separate warnings to be cautious in using any of the ratings. Ample safety factors must be applied, even when the basic reference, the operating mill, is well authenticated.

Classification of materials as they should be considered in selection of proper grinding equipment follows:

Hard, friable, abrasive: Coke, feldspar, quartz, cement clinker.
Hard and tough: Metals, mica (hard rubber, wood).
Medium hard, friable: Limestone, barite, coal, phosphate rock.
Soft, friable: Salt, sulphur, clay, borax.
Fibrous: Asbestos (grain, leather, bone, roots, wood).
Soapy: Talc, graphite, gypsum.
Sticky: Resins, asphalt, certain oxides and chemicals.

Size of feed has a different incidence upon dry-grinding capacity according to the type of machine used. In general the higher the speed at which load is applied, the heavier the comminuting body, and the softer or more friable the material ground, the smaller the effect of feed size. Thus performance of a hammer mill is much less affected by variation in feed size than is a tumbling mill.

For hammer mill see Sec. 5, Figs. 58, 59. Table 18, item 88, shows a small effect only in a rod mill grinding soft and coarsely brittle petroleum coke. Table 20 shows a definite effect on tonnage and power consumption with a large tumbling mill grinding clinker, but the effect is in no way proportionate to the change in limiting size of feed. Table 21 shows similar results with a smaller tumbling mill grinding limestone. On clinker (Table 20) there was an increase of 30% in capacity of a mill consuming 400 hp., or a saving of 7.2 hp-hr. per ton, by reason of a preliminary reduction through the range from <3/4-in. to <6-m. Such reduction can be done for half or less of this cost in a fine crusher. The difference was even more striking in the case of limestone (Table 21). Table 18, item 213, shows a saving of slightly more than 50% in power consumption with a small tumbling mill for reduction in feed size from <2-in. to <20-m. A large part of this saving would have been made if the feed-size reduction had been to 1/4-in only (see Table 21), and the relatively costly preliminary reduction from <1/4-in. to <20-m. could thus have been saved. For general discussion see Sec. 5, Arts. 13 and 14.

a Grindability increases with magnitude of rating number.

Moisture. Control of moisture in feed and throughout the circuit is of vital importance in dry grinding, particularly in circuits containing screens. Some types of mills will tolerate more moisture than others, and the tolerance in a given circuit differs with the material fed. The dry pan, hammer mill, and rod mill can tolerate the most moisture; tube mills probably the least. In a way this is no more than saying that mills doing coarse grinding without screens can tolerate sensible quantities of moisture, but that moisture in quantities greater than $^1/_2$% for softer materials of 2.6 sp.gr., ±1% for hard silicates, and 1 to 1 $^1/_2$% for bituminous coal, is fatal to efficient fine grinding with or without screens, unless some provision is made to take care of it. If a mill is air-swept at atmospheric temperatures, the feed (2.6 sp.gr.) may contain as much as 3 to 6% moisture, and if swept with hot gas, may contain from 20% in a tumbling mill to as high as 40% in a hammer mill.

The moisture will, however, affect capacity and power consumption, even though the mill still continues to grind. Thus, as shown in Table 18, item 77, a 5-roll Raymond mill with built-in classifier lost 25% in capacity and suffered an increase of 50% in power consumption per ton as the moisture content of the bituminous coal received rose from 0.8% to 4%; the loss for an increase to 1.2% was 14%. An 8-ft.×36-in. Conical pebble mill, with a gas flame introduced at the feed end, and in closed-circuit with a reverse-current classifier, ground <$^3/_8$-in. clay for pottery, with 25% moisture, at the rate of 1,600 lb. per hr. to 95% <200-m. At 12% moisture, capacity was 2,200 lb. per hr. to the same fineness. The same mill without air classifier and heat could not grind this clay if the feed contained more than 3% moisture.

Predrying is preferred for materials subject to contamination by direct contact with gases of combustion, or where high vent loss is inevitable and the product is valuable, or when mill drying might cause harmful chemical reactions or physical changes. Certain types of mills are so designed that passage of gas through the mill during operation is impractical or substantially ineffective.

Effectiveness of drying. Capacity of a 5-ROLL RAYMOND HIGH-SIDE MILL grinding Missouri clay to 99.5% <325-m. was increased 30% by drying the feed, which initially contained 5% moisture. Caking in the mill was eliminated and uniformity of product was increased. Capacity of an 8-ft. CONICAL PEBBLE MILL, grinding feldspar in closed-circuit with a mechanical air classifier, but operating with no air passing through the mill, was increased 25% when moisture was reduced from 8% to <1%. Capacity of a Fuller SCREEN-TYPE MILL grinding cement rock was increased 50%, screen maintenance was reduced to 20% of the former figure, and power decreased more than 25% by predrying.

Size of product has, probably, the greatest effect of any single factor on the capacity

of a grinding machine. For general discussion of the effect in tumbling-mill operation see Sec. 5, Art. 13. For effects on performances of a variety of mills see Table 18, items 4, 16, 20, 21, 37, 60, 61, 64, 93, 100, 102, 117, 118, 141, 148, 164, 174, 175, 176, 177, 178, 179, 186, 189, 190, 197, 205, 206.

A Bradley Hercules mill grinding cement clinker handled 150 bbl. per hr. with 4 ½-m. screens on the mill, 135 bbl. per hr. with 6-m. screen, 125 with 8-m., 120 with 10-m., and 110 with 12-m., drawing about 300 hp. in all cases. Screen maintenance was unduly high with screens finer than 8-m.

Effect with a Conical ball mill grinding cement clinker is shown in Table 22. Reduction in tonnage was 23% for a change in percentage of <200-m. from 82 to 93, holding feed size constant at <¼-in.

Table 22. Effect of change in size of product on performance of a Conical mill in preliminary grinding of clinker a

Hp-hr. per bbl.......	1.5	2.2

a Circuit closed by Hum-mer screen; <1-in. feed; 21 r.p.m.; 4-, 3-, and 2-in. mixed ball charge; 8-ft. ×30-in. mill.

Small changes in limiting size of product are of considerable importance from the standpoint of capacity Fig. 35, which gives the relationship between percentage and power consumption, may be interpreted in terms of capacity on the basis that capacity is inversely proportional to power consumption. It follows that full advantage should be taken of tolerances in limiting-size specifications; 2 or 3% oversize on the limiting screen as against 100% through adds materially to plant capacity. See also Table 18, items 4, 176, 177, and 205. The effect is less the coarser the nominal limiting mesh; *cf.* items 60 *vs.* 61, and items 99 and 177, Table 18. The explanation is, of course, that in grinding the last small fraction of material coarser than limiting size, a large amount of new surface is produced from the material already smaller than the limiting screen, and this requires both time and energy.

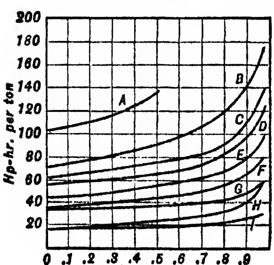

Fig. 35. Product size *vs.* power consumption (*after Farrant, 18 ICE 56*).

Machine. Capacity of machines per unit of weight and, in general, per unit of energy input, increases with the speed of the moving parts. This is particularly true in the reduction of coarser sizes to coarsely fine sizes (preliminary or first-stage grinders), and would probably be true of fine reduction also, if mechanical means for utilizing very high speeds in such service were developed. On the other hand, the wear of high-speed comminuting surfaces is considerably greater for a given reduction of a given material than it is for the slower machines, and it in-

creases disproportionately both in extent and harmful effect as the abrasive character of the material increases. A general rule, that was much quoted and largely adhered to for many years, was not to use hammer mills for materials containing more than 5% of free abrasive (siliceous) material, and, whereas this maxim has been more honored in the breach than in the observance of recent years, owing to advantages gained in shape of product, it still holds when such special advantages are absent. The fixed-path mills of intermediate speed are not so closely confined to soft or friable feeds, but they wear badly with hard abrasive material, and lose capacity rapidly in the process. The relatively slow speed tumbling mill is the only type that is continuously efficient with hard and abrasive feeds. Table 23 groups the various dry-grinding mills on the basis of speed of the working surfaces, and lists various attributes. Table 24 lists the classes of mills normally used in grinding various materials. The order of listing of classes is not necessarily the order of use. High-speed and medium-speed mills are normally used for grinding materials of grindabilities equivalent to medium limestones and softer, when fineness specifications are moderate; tumbling mills predominate for the harder materials, and are almost universally used to fulfill specifications for ultrafine products, unless the material is extremely friable.

Table 23. Classes and attributes of dry-grinding mills

Item	Class I	Class II	Class III
Relative speed	Slow	Medium	High
Grinding action mainly by:	Attrition; compression; impact	Compression; attrition	Impact; shearing; attrition
Mills	Tumbling, *viz.*, ball, pebble, tube, rod, batch; pan	Rolls; ring-roll; ball-bearing; buhr	Hammer; disk; cage; jet
Types of materials ground to best advantage	Hard, abrasive, friable	Medium-hard, nonabrasive, friable	Soft and friable; or tough nonabrasive; fibrous
Advantages	Low maintenance; efficiency increases with use *a*; minimum contamination; easy to control; little attention required; character of product	Low power consumption; low floor space	Low first cost; low power consumption; low floor space; character of product
Disadvantages	High first cost; high power consumption in some cases; floor space	High maintenance on hard materials; efficiency decreases with use; character of product	Excessive maintenance on hard materials; efficiency drops with use; lost time high

a Due to wear-in of tumbling load; dependent on proper rationing (see Sec. 5, Art. 6).

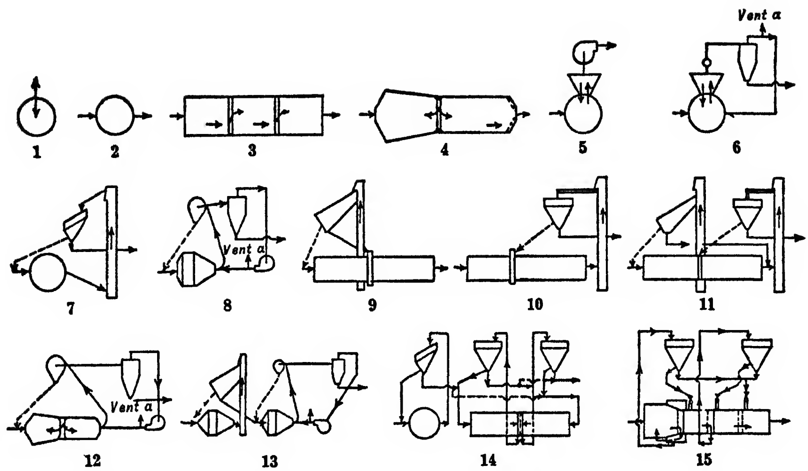
Sizers. Rarely is material ground as effectively in a once-through open-circuit operation as when the grinding circuit comprises a grinding machine and one or more separators designed to remove product that is finished on a size basis, and to return unfinished material to the grinding zone. The separators in dry-grinding circuits are screens and air classifiers. They may be built into the grinding-machine structure, or be wholly separate.



1. Batch operation. A suitable amount of material is charged; the mill is run for a predetermined time, then is stopped and dumped. Tumbling mills, pan, and chaser mills are so run.

2. Open-circuit operation. Material is fed and discharged continuously, once-through. All types of mill, except batch tumbling mills, can be so operated; success varies.

3. Compartment mill with tumbling-media decrease in size from compartment to compartment. Useful for relatively coarse feed and large limiting reduction ratio (Sec. 4, Art. 2).

4. Compartment mill with screen in the division head, affording internal separation and return of oversize. Efficiency is considerably higher than the arrangement shown in (3), where oversize particles can pass from one compartment to the next.

5. Air sweeps through the grinding zone. Separation and recirculation in the mill are more or less thorough according to the interior arrangement. This arrangement applies to hammer mills, roller mills, ball-bearing mills, and tumbling mills; its greatest application is in unit pulverizing of fuels for firing boilers, kilns, furnaces, and the like.

6. Closed-circuit system typical of roller, hammer, ball-bearing, and ring-roll mills. Separation is made by air-sweeping the mill. Vent *a* is to bleed off moisture when hot gas is used.

7. Common practice with most types of mills. Gravity fall from mill to elevator, thence to a screen, with oversize returned to mill. Substitution of an air classifier for the screen is made for fine products.

8. Rough (reverse-current) classification in mill, air transport to external finishing classifier, oversize returned to mill; collector separates product from carrying gas. Vent *a*, see (6).

9. Compartment mill with first compartment in closed-circuit with an external screen, oversize returned to feed stream, undersize to a scoop which feeds second compartment. Suitable for ultrafine grinding; compartments multiplied if necessary.

10. Compartment mill, with second compartment in closed-circuit through an elevator with an air classifier. Product is more closely sized than is possible in (9).

11. Combination of (9) and (10), routed to give a closely sized feed to the second compartment, which increases grinding efficiency, and eliminates tramp oversize.

12. Compartment mill with internal screening; return of oversize to the discharge end of the first compartment; finishing in the second compartment, with roughing out of fines, and finished separation in an external classifier which returns oversize for repassage through both compartments.

13. Two-stage grinding in separate circuits, the first closed by a screen through an elevator; the second having internal and external classification (*cf.* 8). Maximum flexibility in installation and operation; desirable when coarse feed is reduced to a very fine product.

14. Three-stage grinding in semiseparate units with individual external separators. Primary circuit closed by a screen; undersize to coarse end of a double-ended ball mill with central partition and central discharge; balls in this compartment are larger than in the other; circuit closed, via elevator, by an air classifier delivering undersize to a second classifier which closes circuit on the second compartment via a second elevator, and which makes the finished product of the circuit. In a modification (dotted flow lines) both classifiers make finished products, part of the product of the preliminary mill being by-passed to the fine end to balance the circuits.

15. A four-compartment mill. Circuit on first compartment closed by peripheral screens, sending undersize to an air classifier which delivers oversize to second compartment; this operates once-through, and delivers to a second air classifier, which feeds oversize to third compartment, likewise operated once-through, which delivers to fourth compartment operating open-circuit on this feed and the fines of both classifiers.

FIG. 36. Dry-grinding circuits.

The arrangements of flow using separate machines for the two functions are legion. Several are shown in Fig. 36.

Efficiency of separation. The separator need not be highly efficient in removing all of the material finer than a prescribed separating mesh in order to perform its function satisfactorily. The primary purpose of separation is to clear the voids between the particles to be broken to such an extent that the interstitial filling will not act as a cushion protecting these particles from the comminuting forces. The sizes important to remove are those near the separating size, since they have the greatest filling and cushioning effects. More fines may be permitted to return when the reduction per pass is large than when it is small. Removal of fines from initial feed is unnecessary, therefore, unless the percentage is unusually large, or a small reduction only is contemplated. Thus at International Nickel Co. (E. H. Rose, *PC*) it was found that with 19% of finished (<65-m.) product in <3/8-in. feed to wet-grinding ball mills, capacity was substantially identical whether new feed was introduced into classifier or mill. The data bear equally on dry grinding, except that in dry grinding the finest material agglomerates and coats balls and should, therefore, be eliminated from the return.

Screens *vs.* classifiers. The choice is not clear-cut. Screens are used perforce at sizes coarser than 10-m. because of limitations of the classifier (see Sec. 9). Classifiers, on the other hand, preëmpt the field at sizes below about 48-m., because of the tendency of screens to blind if anything above a barest minimum of moisture is present. In the twilight zone (10- to 48-m. separations) the weight of practice is to use screens as far down as can be done. See Table 18, items 67, 68.

Open *vs.* closed circuit. The weight of experience is in favor of closed-circuit operation, except when an ultrafine product, beyond the lower limit of effective air classification, is required.

At Medusa Portland Cement Co., York, Pa., an 8×7; 7×17-ft. two-compartment mill was converted from open- to closed-circuit operation. The feed was <2-in. kiln-run clinker; product open-circuit, 88% to 90% <200-m.; speed, 22 r.p.m.; 600 hp. motor; actual power draft about 550 hp.; ball charge, preliminary compartment, 5-in. to 2-in., steel, 22,000 lb.; finishing compartment, 7/8-in., 70,000 lb.; ball consumption, 0.55 to 0.66 lb. per bbl.; manganese-steel liner life, preliminary compartment, 4 yr.; finishing compartment, 12 yr. Before the change, an Electric Ear was installed. Average capacity at that time was 71 bbl. per hr. Sound control steadied the fineness from ±4% difference in <200-m. to ±1% difference. When the mill was changed over, a 16-ft. Sturtevant air classifier was installed, with a 75-hp. motor. A 10-hp. motor was required on the elevator from the mill to classifier. Oversize return from the classifier was at first sent to the second compartment, as in item 10, Fig. 36. Later, oversize was returned direct to the feed end of the preliminary compartment, with improved results. Average capacity open-circuit was 71 bbl. per hr. to 89.5% <200-m.; afterward capacity averaged 69.5 bbl. per hr., but fineness was 97% <200-m., 94% <325-m., and 1,650 to 1,700 sq. cm. per gm. surface area.

At the Medusa Portland Cement Co. plant at Toledo, Ohio (*35 #2 PQ 38; 45 #9 RP 34*), 7×22-ft. two-compartment mills, with center feed and peripheral discharge, operating open-circuit, ground clinker to 92% <200-m. (1,425 sq. cm. per gm.) at the rate of 50 bbl. per hr. per mill. Placing an 18-ft. Raymond air classifier in closed-circuit increased capacity to 60 bbl. per hr. Conversion of one mill to a preliminary ball mill, with feed entering at each end and product discharged at the center, and of the other two mills to plain ball-tube mills; running the preliminary mill in closed-circuit with vibrating screens, and the 18-ft. classifier in closed-circuit with the ball-tube mills, and placing an Electric Ear on the primary, gave the primary a capacity to <20-m. of 150 bbl. per hr., while the finishing mills averaged 79.4 bbl. per hr. per mill, 98% <200-m., 91% <325-m., surface area 1,684 sq. cm. per gm.; consumption of 7/8-in. balls, 0.11 lb. per bbl. The air classifier required 125 hp. and elevators and conveyors 50 hp. The preliminary ball-tube mill was then replaced by 2 @ 9-ft. ×48-in. Conical ball mills, with Feedometers and sound control, each mill operated with 250-hp. motor and in closed-circuit with 3 @ 4×5-ft. Hum-mer screens. Capacity was 100 bbl. per hr. to 95% <20-m., with more than 50% <200-m. Conical-mill motors were 250-hp.; those on the ball-mills, 400-hp. synchronous.

a 7×26-ft. two-compartment finishing mill with air classifier.

Table 25 shows an increase in capacity, fineness, and strength of cement following a change from open- to closed-circuit operation. See also Table 18, items 32, 33.

In mills in which the gradient of material determines throughput, and in which there is no internal size guard, a once-through product has more or less tramp oversize, and correspondingly less or more ultrafine material, according to feed rate. The same mill operated closed-circuit with a screen makes a product without tramp oversize, and of a mean size nearer that of the screen aperture the larger the circulating load; *i.e.*, the percentage of very fine material produced depends more upon the rate of passage of an individual particle through the mill than upon the total time spent in the mill. Some ultrafine is pro-

duced no matter how high the circulating load, but a mill which permits the use of large circulating loads reduces overgrinding considerably. Conversely a mill run in closed-circuit with a classifier, with low circulating load, and with tramp oversize excluded, produces a large quantity of ultrafine. A combination of screen and air classifier makes it possible to produce various degrees of fineness simultaneously.

Conditions of operation of a dry-grinding circuit have a material effect on performance. The principal factors are method of feeding, mill speed, kind of grinding media, and temperature.

Method of feeding. If a dry-mill feed were a constant quantity as regards physical properties, size, size distribution, moisture content, and temperature, and atmospheric conditions and the state of the mill itself remained constant, then a constant feed rate would be all that was needed to make a product of consistently uniform size characteristics. Unfortunately none of these things is true, and, as a result, the method of feeding becomes one of the important elements in mill operation.

The characteristics of the product of any grinding mill at any given time depends, all other things being equal, upon the amount of material within it undergoing comminution. High-speed mills reflect this in-mill load sharply in the power draft of the driving motor, hence nominal variation of feed rate in response to indications of instruments on the power line is the usual method of control. Tumbling mills show smaller power fluctuations in reflection of load, and their feed can be and is similarly regulated, but not so satisfactorily. Automatic controls have been developed for both types of mills, which operate with varying degrees of success.

Controls. A pneumatic arrangement on the air classifier of the high-speed air-swept mill has proved satisfactory. With increase in loading of the air stream, pressure changes; this change initiates a mechanical reaction which raises or lowers a ratchet on a constant-speed mill-feeder shaft. An alternative arrangement, utilizing the same pressure difference, causes a shutter to pass over a photoelectric light-actuated cell, thus actuating a relay which controls the feeder motor. Since the power required of a high-speed mill varies directly with the load in the mill, electrical devices, actuated by relays sensitive to changes in the power, are used to actuate the feeder to maintain reasonably stable conditions within the mill. Changes in the settings of these power-actuated controllers are required from time to time to compensate for change in wear of the grinding elements. Where there is a floating material load in a mill, as a ball mill, Frisch (*U. S. Patent 2,291,618*) describes blowing air into the mass and, through the differential in pressure caused by slight differences in material level, actuating a relay system that controls the feeder to maintain the level constant. Sound control (Sec. 5, Art. 18) is applicable to both fixed-path and tumbling mills. Thermostatic controls are used with all air-swept mills in which material is being dried as ground. Control is based on temperature at the mill outlet; temperature or volume of the entering gas is varied in response in order to so vary drying conditions as to maintain discharge temperature constant.

Bins. Even with controls as described, operating difficulties may arise owing to improper bin design which causes bridging or flooding. Flooding tendency is decreased by making two adjacent sides of the bin vertical. Multiple discharge openings are best for bins of large capacity. For steady feeds a Constant-Weight Feeder together with a bin-rapping device, or a feed-failure alarm is of considerable help.

Cost of feed-control devices is 1 to 5% of the cost of the grinding installation; they pay out quickly in resultant economy of operation.

Speed. Capacity or, correlatively, fineness of product increases with speed of all dry-grinding mills, within the limits of the operating range. In most fixed-path mills excessive speeds cause excessive wear and vibration; speeds should not exceed those recommended by the manufacturers. In tumbling mills, speed too much in excess causes partial centrifugal cling; below this point but in the cataracting range capacity is low and ball and liner wear high by striking of balls high on the breast of the mill; as speed is further reduced below cataracting, capacity rises and wear decreases. Hammer-mill speeds that are too low cause too great penetration of the hammer circle, with a sharp drop in capacity and with high wear; within the operating range, the effect on fineness of product is shown in Table 26. See also Sec. 4, Art. 9. Higher speed is required to maintain hammer extension with coarse feed than with fine (*45 CME 230*).

a Limestone; bars spaced 1/8-in.

Grinding media and wearing surfaces. Wear of grinding surfaces is important not only from the standpoints of the cost of replacement parts, and of labor and time lost in making the replacement, but also because, in any machine, the relationship of the parts to each other is changed thereby, and this change affects performance.

Rolls, ring-roll and roller mills tend to corrugate, or to wear more on one side than on another. Rings usually outlast rolls. Balls in ball-bearing machines wear faster than the races, and decrease in size changes the surface of contact against the races. When corrugation occurs or wear is one-sided, effective grinding surface is reduced, and with it capacity. For wear in hammer mills see Sec. 4, Art. 9. Liners in tumbling mills lose longitudinal ribbing; the charge of tumbling media becomes smaller in average size, and may or may not take on a size distribution less favorable to the grinding task, according to how accurately it was rationed originally. Tumbling media frequently wear into irregular shapes, which are not, in general, as effective as spheres or round rods (*124 J 695*). See Table 20 for effect of change in ball load in one case. Figs. 37 and 38 show effects of variation in size and proportioning of balls composing a load on the size and size distribution of products. See Sec. 5, Arts. 5 and 6 for further discussion of changes in performance due to wear.

B 67% of 5-in. and 33% of 4-in. balls; feed rate, 2.2 t.p.h.

FIG. 38. Ball size *vs.* size of product.

Wear in dry grinding generally is much lower, in all types of machines, than in wet grinding. Liner lives in tumbling mills grinding reasonably soft materials may be 5 to 20 yr.; ball wear ranges from 0.1 lb. per ton or less for soft materials to 3.5 or 4 lb. for hard abrasive materials ground fine from coarse feed. Wear in air-swept mills tends to be less than in those not so operated.

Segregation of tumbling media of mixed sizes occurs to a greater or less degree during rotation, the small sizes going to the middle at low speeds and to the periphery at high (*69 A 200*); best admixture in a transverse plane apparently occurs at a speed just below that at which cataracting starts. There is also a tendency toward longitudinal segregation, with the large balls going toward the ends of the charge. A shell with conical ends and relatively short cylindrical section tends to overcome both of these segregations at the higher operating speeds by a combination of effects. First, in cascading, the conical ends cause the end balls to follow a curved path directed toward the trunnions at the top of the downward travel, and toward the cylindrical section at the bottom, as indicated in Fig. 21. Second, the large balls roll over the irregular surface of the load more readily and, therefore, faster than the small. Hence the large balls run out farther at the toe of the load, which results in their coming up on the outside of the cylindrical section. This serves also to keep them from building up a concentration at the ends. It follows that a short conical mill can be run at higher speeds than a cylindrical mill without losing the impact impulses of the large balls by having them go to the center of the tumbling mass. The short-cylinder conical shell also exerts a wedging effect on the load, which tends to carry it higher at a given lower speed than would otherwise occur, owing to slip; this increases both the in-load pressures (Sec. 5, Art. 3) and the avalanching impulses, and thus increases comminution. The effect of the cone ends in preventing longitudinal segregation is present irrespective of the length of cylindrical section.

Temperature at which charge is ground may have marked effects on the grinding rate by inducing brittleness or reducing stickiness, particularly with organic materials. Conversely, heating may impart brittleness, as with quartz, certain brasses, etc. Materials may be cooled by jacketing the mill, or by mixing dry ice or liquid air with the material. Heating is done by sending hot gases through the mill, or preheating the solid, or both. In grinding cement clinker, temperature may rise to such an extent as to be harmful to the cement, and to reduce grinding rate by causing ball coating.

Power consumption in dry grinding varies according to the material ground, the size of product, the machine in which the grinding is done, and the apparatus used to close the circuit.

Material ground. Classification of materials as to performance in dry grinding depends not only upon the grindability of the material but also upon the size to which it is ground and the method used to grind it. Soft materials are easier to grind to 8- to 20-*mog* than are rocks of average hardness, if medium- or high-speed fixed-path machines are used together with auxiliary apparatus that separates finished sizes rapidly and reasonably thoroughly, but some soft substances, *e.g.*, talc, clay, and some of the lighter carbonaceous materials, are more difficult to grind to 100- or 200-*mog* or finer than average rock is. This is due, in part at least, to inefficiency in separation, and to the cushioning effect of the unseparated fines in the return product. Tough, soft materials may require upward of 2,000 hp-hr. per ton for reduction to fine powders, but brittle metals such as some cast irons can be reduced to intermediate sizes with little more power input than is required for the harder average rocks.

Table 27. Power consumption *vs.* size of product in dry grinding

Mog	Hp-hr. per ton *a*	
	Easy grinding	Average resistance
8 to 14	10	20
20	15	25 to 30
48	20	45
65	25	50
100	30	55 to 60
200	45 to 50	90 to 100
325	60	125 to 150

a These figures are averages of from 5 to 35 or 40 cases for each *mog* and classification of material. The values for 100 and 200 *mog* are most reliable. The extreme range, however, is almost ±50% of the tabular values, representing, in part, differences in the responses to grinding forces of the materials classified in the two groups, and in part, differences in efficiency of the grinding operations.

Size of product. Average figures for power consumption in grinding materials of low resistance and those of average resistance to different *mogs* (0 to 2% on the nominal separating screen) are given in Table 27.

Grinding machine. The lowest power consumptions in coarse grinding of soft materials (Table 27) correspond to substantially once-through operations in mills having built-in screens and provision to aid presentation of material to the screens by mechanical means or strong air currents. For hard materials, the tumbling mills with peripheral screens, or short ball mills in circuit with screens, require the least power. Fine grinding of soft but resistant materials requires much power, no matter what type of machine is used. The weight of the evidence of Table 18, considering the soft carbonaceous materials, clays, gypsum and talc, is that the fixed-path mills do the job with the least power consumption. Even more definitely, fine grinding of hard materials consumes the least power when done in tumbling mills. Comparative data on tumbling mills in such service are found in items 95, 113, 114, 127, 130 and 131. Power consumption for batch grinding is invariably high relative to continuous operation when comparison is on the basis of product passing a limiting screen. On the other hand, if credit were given for ultrafineness, the discrepancy would not be so large.

SECTION 7

SCREEN SIZING

1. INTRODUCTION

Definitions. SIZING is the process of dividing a mixture of grains of different sizes into groups or GRADES whose characteristic is that the particles therein are more or less nearly of the same size, that all have passed an aperture of certain dimensions and failed to pass through some smaller aperture. The screen through which the particles have passed is called the LIMITING SCREEN; that which has retained them is sometimes called the RETAINING SCREEN. CLOSE SIZING is practiced when the apertures of limiting and retaining screens are nearly the same. The sized product is SHORT-RANGE. A mass of particles is said to be a NATURAL or LONG-RANGE PRODUCT when it has all passed a given limiting screen but has been subjected to no further treatment. Material that stays on a given screen is the OVERSIZE or PLUS ($>$) of that screen; that passing is the UNDERSIZE or MINUS ($<$). A SIEVE SCALE is the list of apertures of successively smaller screens in a step-sizing operation. The SIEVE RATIO is the ratio of the aperture of a given screen in a given sieve scale to the aperture of the next finer screen. PERCENTAGE OF OPENING is the ratio of the combined area of the openings to the total area of the screening surface. CLASSIFICATION is a process of approximate sizing; it is discussed in Sections 8 and 9.

Purposes of screen sizing: (*a*) to SCALP off the coarse end of a long-range product, usually for further reduction; (*b*) to cut off the fine end from crusher feeds and thus save power and prevent over-grinding; (*c*) to grade broken rock products into commercial sizes, as for road metal, ballast, concrete aggregate, sands, and the like; (*d*) to perform a step in a concentration process, *e.g.*, to size before jigging (see Sec. 11, Art. 2).

Principles. The fundamental function of screening is to pass undersize particles through the apertures and reject oversize particles. The particles must therefore be brought to the openings and be presented thereto at such a velocity and in such direction that passage of undersize will not be hindered or prevented by rebound from the edges or walls of the opening. If every particle of undersize could be brought to an opening individually, at substantially zero velocity, in a direction perpendicular to the plane of the opening, and with the center of its least projected cross-section in line with the center of the aperture, and if the screening surface had no thickness, every such particle would immediately pass. But tonnage requirements forbid individual and low-velocity presentation, while mechanical considerations prevent perpendicular presentation and the use of screening surfaces of gossamer thickness. Practically, particles are crowded and continually interfering at the apertures, they are presented at considerable velocity, in a direction nearly parallel to the plane of the screen surface, with their maximum rather than their minimum projected surfaces generally parallel to the plane of the screen, and the screen opening has a depth frequently greater than the greatest dimension of the particle of undersize. Many undersize particles are thus excluded for a considerable time from access to an opening; others come to the opening from such a direction or with such orientation or at such velocity that they fail to enter; others, entering, are delayed in passage or stopped by friction against the walls of the opening or, if on a vibrating screen, may actually be ejected.

Chance rules the approach of a particle to hole or imperforate surface and the probability that the lowermost point of the approaching particle will strike hole rather than screen fabric is proportional to the percentage of opening in the fabric. Chance coupled with the

relative dimensions of particle and opening rules in determining the passage of a particle presented to an opening. The problem may be stated in mathematical form as follows: If, in Fig. 1, the full-line square whose side is l represents a square screen aperture and the circle a spherical particle whose diameter is l/n (n being any number greater than l), then the probability of passage without touching the side of the aperture is proportional to the ratio of the area of the smaller square to the area of the larger, or $P = [(n - 1)/n]^2$ and the probability that the sphere will touch the side on presentation is $(1 - P)$. On the assumption that if the center of the sphere falls within the inner square in Fig. 1, it will surely pass, while if it falls without this square, it will fail to pass, the values of P for different values of l/n are measures of the ease of random passage of spherical particles of l/n diameter through l-sized square apertures, and $1/P$ gives the number of such apertures side by side that should be provided to insure passage. The first part of the assumption is true if l^2 is the area of the opening projected on a plane at right angles to the path of the particle; the second part must be modified in favor of passage, because although a particle presented with its center in the space between the squares will rebound in a direction and through a horizontal distance dependent upon the shape of the edge of the aperture, the angle of approach, the velocity of approach, and the shape of the particle, nevertheless some of the rebounding particles will fall with their centers within the inner square and pass. Unfortunately the number and nature of the qualifications that must be applied to this mathematical analysis in actual screening are such that no approach to a practical measure of capacity by a modification of it has yet been made. It is useful to indicate the probable effect on rate of screening of the ratio of particle size to aperture. To this extent Table 1, derived from the formula, is illuminating. It shows that as the particle size approaches that of the aperture the difficulty of passage becomes extremely great, even excluding all factors other than pure chance that militate against passage. Warner (*70 A 631*) gives the data summarized in Table 2 as the results of a test in which a sample of broken rock was screened on a standard 4.70-mm. testing sieve in a Ro-Tap shaker (Sec. 19, Art. 12), and the undersize products passed during the successive screening intervals were separately collected, weighed, and subjected to analysis on a 3.33-mm. screen. This work is qualitative confirmation of the theory, modified, however, by the practical elements of crowding, particle velocity, etc., as previously enumerated. The column headed "Increment per sec., grams >3.33-mm." holds the key to the operation from the point of view of screening rate. In the first three intervals the passage of even the smallest particles was interfered with by the mass of smaller material going through. By the time the fifth interval was reached most of the <3.33-mm. material had passed and by the end of this interval the bulk of the finer part of the >3.33-mm. material had also gone through. From that time there was a marked decrease in the rate of screening corresponding remarkably in order to the last four items in Table 1 and indicating that the material passing the screen in this part of the operation was of a size about 0.9-times the diameter of the screen opening and upward.

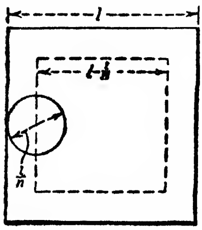

FIG. 1.

Table 1. Probabilities in screening

Size of grain, l/n-in.	Probable chance per 1,000 for unrestricted passage through l-in. square	Probable number of apertures in path of particle required to effect passage
0.001	998	1
0.01	980	2
0.1	810	2
0.2	640	2
0.3	490	2
0.4	360	3
0.5	250	4
0.6	140	7
0.7	82	12
0.8	40	25
0.9	9.8	100
0.95	2.0	500
0.99	0.1	10,000
0.999	0.001	1,000,000

An important condition affecting capacity in close sizing is the proportion of particles in the feed that are nearly the same size as the aperture. Undersize much smaller than the screen openings passes through very rapidly, so rapidly in fact that, if it is given free access to the holes, it goes through almost like water, and no normal variation in the amount of such material has any effect on screen capacity. Likewise particles much coarser than the openings, when sliding over a screening surface, have such large interstitial spaces in comparison with undersize particles that the latter pass down freely to the screen surface. But when the proportion of particles of a size near that of the screen aperture is large, these particles, which have interstitial spaces that are relatively small, hold back the fine material from the screen; the particles only slightly larger than the screen apertures wedge in and cause blinding, and those only slightly smaller than the aperture pass through with diffi-

culty, therefore slowly. The result, as shown by Warner's work and the above theoretical analysis, is marked reduction in screen capacity. Experience has shown that this "critical" size ranges between approximately 50% larger and 25% smaller than the aperture.

The velocity and direction of approach of particles to the aperture have a marked effect on screening rate. If a spherical particle is traveling at a given rate along a screening surface whose apertures are several times the diameter of the particle, as in Fig. 2(*a*), its path upon leaving the support of the screen fabric will be somewhat as illustrated and the particle will pass through. With a smaller aperture the same particle will strike the far edge of the opening. If the particle were perfectly spherical and elastic and the aperture had square edges and vertical sides, it would also pass, as pictured in Fig. 2(*b*). But with irregular particles and with apertures having rounded edges and converging sides, there is every reason to expect that a particle following the path illustrated would fail to pass. If the initial approach of the particle is from above and at an angle to the screen surface as illustrated at (*1*) in Fig. 2(*c*), the direction of approach and high velocity both aid in passing it, if it strikes an opening, but if it fails to do so, as at (*2*), then high velocity, by causing it to bound, will tend to defer its opportunity to pass and thus decrease screening rate. Since the percentage of opening in screens is often less than 50, the evil effect of bounding may be expected to overbalance the good.

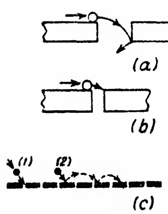

FIG. 2.

When, as in all practical screening operations, a mass of particles many grains deep is presented to a screen surface, coarse and fine grains are likely to be mixed indiscriminately, with the result that many oversize particles are in contact with the screen and many undersize particles are supported in the mass above and away from the screen surface. If the particles are free to move among themselves, *i.e.*, if the material is not sticky, any subsequent movement of the mass will cause rearrangement. If the movement is sufficient to enliven the mass thoroughly without lifting it bodily from the screen, stratification occurs, with the finer particles at the bottom and the coarsest on top. Such stratification is essential to screening and is as much the purpose of the motion imparted to screening surfaces as are transport of oversize and prevention of blinding. Excessive movement, while it increases the ability of the screen to move material across its surface, defeats stratification and thereby decreases screen efficiency.

2. CAPACITY AND EFFICIENCY

Efficiency. Methods of reckoning screen efficiency are not uniformly established. A common method (UNDERSIZE RECOVERY) is to express it as the ratio of the weight of undersize obtained to the weight of undersize in the feed. This latter figure is determined by screening a feed sample on a hand screen of the same aperture as that of the screen under investigation, or by making a sizing test of the feed on the usual testing sieves, interpolating for the aperture of the operating screen and multiplying the percentage of undersize thus obtained by the tonnage treated. A similar measure is obtained by making screen analyses of representative samples of feed and oversize and applying the recovery formula (Sec. 19, Art. 24). Thus $E_1 = 100[100(e - v)/e(100 - v)]$ where e and v are percentages of undersize in feed and oversize respectively. On this basis efficiencies on well-operated vibrating screens will be 80 to 90% or slightly higher with screen apertures of $^1/_4$-in. or larger but will fall to 65 or 70% at 10-m. with normally low moisture content and will fall well below 60% with any material rise in moisture.

Warner criticizes the use of this formula on the basis of the experimental work shown in Table 2. He argues, correctly, that it does not take into consideration sufficiently the fact that 1-mm. material is readily passed through a 10-mm. screen while 9-mm. material passes the same screen with great difficulty, and suggests that the screen analysis of feed and of oversize concern itself only with the DIFFICULT GRAINS, which he defines for this purpose as those held on the next finer Tyler standard testing sieve whose aperture is less than 83% of the aperture of the screen under investigation. He then applies the recovery formula in the form $E_1 = U(F - O)/F(U - O)$, where F, U, and O are percentages of difficult grains in feed, undersize and oversize respectively. A. D. Sinden (*PC*) also emphasizes the desirability of basing efficiency calculations wholly upon the difficult grains, which he defines as those sized between 0.75 and 1.5 times the aperture; unless a screen is seriously overloaded, varying proportions of grain sizes outside this range have little effect on efficiency. He suggests the evaluation of undersize recovery by the formula $E_1 = 100 [U - (ZC)]/U$, in which C = percentage of difficult grains in feed, U = percentage of true undersize in feed, and Z = decimal fraction of true undersize, based upon the difficult

grains only remaining in the oversize product (see p. 7-64). The above methods of calculation are best applicable to operations aiming at removal of oversize, as waste or for recrushing.

A second method (PERCENTAGE OF REMOVAL) calculates efficiency by dividing the percentage of true oversize in feed by the percentage of feed going into actual oversize product. Adopting Sinden's definitions (above) and letting O = percentage of true oversize in feed: $E_2 = 100[O/(O + ZC)]$. This method is most useful when the object of screening is to remove undesirable fines from a coarser product.

A third method, based on percentage of true undersize found in oversize product, more accurately defines the efficiency of a screen, as distinguished from the quality of its products. This is the system adopted by Allis-Chalmers engineers, efficiency being stated simply as 100 − percentage of true undersize in the coarse product. Accepting Sinden's restrictions to the difficult grains (above), $E_3 = 100[(C - ZC)/C] = 100(1 - Z)$.

Efficiency is markedly decreased by high feed rate, especially if accompanied by high percentages of oversize and difficult grains, because on a heavily loaded screen, fine material has difficulty in getting down to the screen surface and blinding is caused by wedging of particles into the screen openings on account of the weight of the bed.

Fig. 3, from A. D. Sinden (*PC*), illustrates how efficiency is affected both by overloading and by excessive proportion of difficult grains ranging, in this case (with 1/4-in. square-mesh screen), from 3/16- to 3/8-in. The two gravels were tested on a vibrating screen under identical operating conditions. Gravel *A*, containing about three times larger proportion of difficult grains, showed its maximum efficiency at a rate about one-third that of gravel *B*.

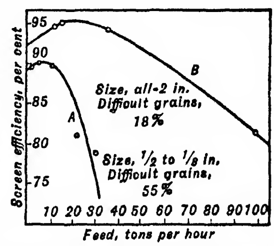

FIG. 3. Effects on screening efficiency of overloading and of difficult grains.

Effect of length of screen on efficiency is shown in Fig. 4, which compares the performance of three vibrating screens, identical except as to length, working on 1/8- to 3-in. gravel; width, 3 ft.; aperture, 1/2 in. square; slope, 17 1/2°; speed, 1,200 r.p.m.; amplitude, 0.154 in.

Feed factors affecting undersize recovery are: (*a*) the percentage of undersize; the less of this the lower the recovery; (*b*) the percentage of near-mesh or difficult grains; the more of this the lower the recovery; (*c*) the moisture content, the degree of stickiness caused by moisture, and the tendency of adhering coatings on the wire to build up; and (*d*) slabby or needlelike characteristics. Dry ore screens better if warm (100 to 150° F).

Capacity of a screen is the tonnage rate at which it performs satisfactorily the size separation demanded. This may be very different from the feed rate.

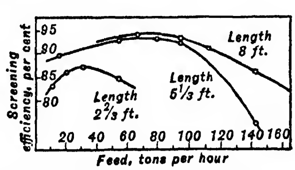

FIG. 4. Length *vs.* efficiency of vibrating screens (*after Sinden*).

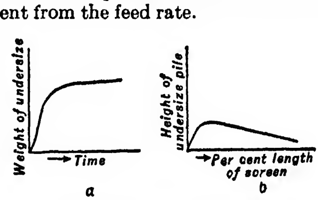

FIG. 5. Capacity curves.

Assume that substantially complete separation of a long-range product is desired at a size about 50% of the limiting size. The behavior of such material in screening may be followed in either of two ways: (*a*) by collecting and weighing the material passing through the meshes in short equal intervals of time from the beginning of screening, in which case a weight-time curve like Fig. 5, item *a*, is obtained; (*b*) by retaining the undersize physically in the place where it fell through the screen during an interval in which a given weight of material was fed at a uniform rate. A profile of such a mass of undersize is as shown in item *b*. Examination of the materials comprising the successive lots in case *a* and of those at different places along the heap in case *b* shows that the early-passing material in both cases is predominantly a mixture of all sizes up to about 70% of the size of the aperture and that the later-passing material grows progressively and slowly coarser with time.

Changes in rate of feed to the screen will not affect the curves materially so long as the material added or subtracted is larger than about 150% of the separating mesh. If the material added or subtracted is less than 70 to 75% of the separating aperture in size, the curves will steepen or flatten respectively in substantially direct proportion to the change. If the feed tonnage of difficult grains is changed the response of the curves is slow.

If the original material tested were bone dry and another test were made with somewhat over 3 or 4% of water added, the slope of the early part of curve *a* would fall, and the height and sharpness of the maximum of curve *b* would decrease. Within a range of moisture content, varying with the mineralogical character of the material, its maximum size, and size distribution, but with a top around 15 to 20% water, the presence of water decreases the rate of passage of undersize greatly. Further increase of water content first restores the passing rate quickly to that of bone-dry material, and thereafter the screening rate rises above that for dry material to an extent dependent upon the size of aperture.

Thus the true capacity of a screen is measured by its ability to pass difficult grains. It is simply a conveyor for EXCESS OVERSIZE (>1.5 times aperture), while EXCESS FINES (<0.7 times aperture) are as so much water.

For capacity ratings of different types of screens see the particular screens.

3. SCREENING SURFACES

The three general types of screening surface are: (*a*) woven wire or silk; (*b*) punched plate or sheet metal; (*c*) parallel bars, rods, or wires.

Screen-size designation. The minimum clear space between the edges of the opening in a screening surface is called the APERTURE OR SCREEN SIZE. Aperture is expressed in several ways; the most accurate, undoubtedly, is to give the dimension in inches or millimeters; the commonest, particularly with woven screens, is to express it as so many MESH, meaning the number of openings in the screen per linear inch. This latter method is definite only when coupled with a statement of the size of wire, or when referred to one of the testing-sieve scales (Sec. 19, Art. 12). When size of wire is given it should be expressed in ordinary units of measure, *i.e.*, inches or millimeters; if gage numbers are used the gage must be named, on account of the differences in dimensions corresponding to the same gage number in different gage scales. See Table 3. Given two of the quantities a = aperture, d = diameter of wire, and m = mesh, the percentage of opening, P, and the other quantity can be determined from the following relations (applying only to square-mesh screen):

$$P = a^2m^2 = \frac{a^2}{(a+d)^2} = (1 - md)^2;\ m = \frac{1}{a+d};\ a = \frac{1}{m} - d;\ d = \frac{1}{m} - a$$

The mesh of punched-plate screens does not mean the number of openings per linear inch but that the aperture has a dimension near that of some woven-wire screen of the stated mesh and usually of medium weight. If the largest and smallest apertures corresponding to a given mesh in Table 4 are averaged, the result will be close to the punched-plate aperture called by that mesh number. Certain districts, notably South Africa, express aperture as SQUARE MESH, *i.e.*, the number of apertures per square inch. Europeans, describing fine screens, commonly state the number of openings per square centimeter. NEEDLE MESH is a number used to designate an aperture and corresponds to that of a needle of the same or nearly the same diameter as the dimension of the opening. See Table 11.

Materials for screening surfaces include cast iron and steel, plain high- and low-carbon steels, manganese steel, chrome-nickel ("stainless") steel, brass, phosphor bronze, Monel metal, nickel, and occasionally other metals and alloys for special purposes; rubber-plated wire screens are available. Silk bolting cloth is used mainly in the preparation of graphite and abrasives, and for the finest sizes of testing screens. The screening surface must be strong enough to carry its load (a fine-wire screen is often reinforced by laying it on top of a coarser and stronger screen) and, so far as possible, it should resist abrasion and corrosion. At the same time it should be cheap. When corrosion is not a factor, screens are normally made of high-carbon steel and in certain cases of special alloy steels. Steel is stronger and resists abrasion better than any other material equally available. Cloth is advertised of wire with 450 Brinell and 225,000 lb. per sq. in. tensile strength. When corrosion must be resisted, iron, copper, bronze, Monel metal, and other alloys are used. Such materials cost more than steel initially and are not so highly resistant to abrasion. Their use is justified only when the final cost, by reason of their greater resistance to corrosion, is less than that of steel screens. Stainless steel is particularly suitable for wet screens since it is resistant to both corrosion and abrasion, and consequently blinds less readily.

Woven-wire screens are made with either square or rectangular openings, and in several different manners intended to prolong their life or prevent displacement of the wires in service. They are regularly obtainable in any length and in widths up to 5 ft.; greater widths are woven to order. Table 3 gives diameters of wires as gaged under various stand-

ards. Table 4 gives dimensions of square-mesh steel-wire cloth corresponding to mesh designations and showing the possible range in aperture for a given mesh cloth of standard manufacture.

To determine aperture of intermediate screens within the ranges given in Table 4 proceed as follows: From Table 3 pick wire of a number included within the range of column 7 of Table 4; substitute the corresponding diameter in the equation $a = 1/m - d$ (p. 06).

Table 4. Mesh and aperture of steel-wire screens

Mesh designation	Range in opening		Range in diameter of wire used		Number of screens in range	Range of wire numbers employed *a*	Range in percentage of opening	Approximate weight, pounds per square foot

shoot wires are crimped to prevent distortion under impact of the load. Fig. 6 shows six typical methods. When a flat-surfaced screen is desired, as for reinforcement under a fine-wire screen, or to prolong life by eliminating upstanding knuckles, a screen may be rolled after it is woven, or a special form of weave may be adopted. Single-crimp wire has been used on a revolving screen on a dredge to prevent blinding.

S.W.G. = English standard wire gage in Table 3.

Flatlock screen (*53 CMJ 360; 54 ibid. 387*) has alternate crimps in each wire to a depth equal to its full diameter; at intervening intersections, a wire has two shallow crimps, one on each side of the crossing wire (Fig. 6, *c*). Thus, every even-numbered warp wire is rigidly locked in a deep groove of even-numbered shoot wires; odd-numbered warp wires similarly by odd-numbered shoot wires. This results in an almost flat surface on one side, with practically all the roughness on the other. Owing to the equalized distribution of wear, this screen retains its mesh accurately until practically worn through. In elongated meshes, only the warp wires have the Flatlock crimp.

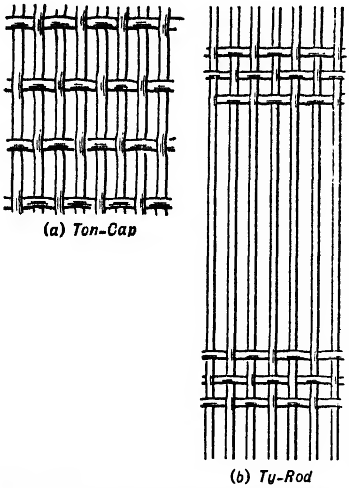

FIG. 7. Elongated-mesh woven-wire screens.

Woven-wire screens with elongated openings have been widely adopted for two principal reasons: (*a*) to compensate for the loss of effective aperture size (and proportion of open area) occasioned when a square-mesh screen is set on a slope, or installed on a horizontal shaking or vibrating screen having a motion oblique to the surface; (*b*) to increase screening capacity, especially with wet or sticky ores, when close precision of sizing is unnecessary. The long dimension of the aperture may be parallel to or across the direction of flow; the former arrangement may afford the larger capacity and is the more suitable for damp material; in the latter position, a screen blinds less and has somewhat longer life and higher efficiency. Warp and shoot wires may have the same or different diameters; in the latter case, the shoot wire is the larger.

Ton-Cap screen (Fig. 7, *a*) has elongated rectangular openings, of which the length is (approx.) 3 1/2 to 4 times the width. Standard widths of opening range from 0.919 to 0.007 in. in about 36 steps. Percentage of open area ranges from 21.1 in extra heavy screen of the smallest

aperture to 74.2 in light-weight screen with the largest aperture; for intermediate sizes and weights, open area averages about 45 to 55%. In ALASKA-JUNEAU mill, a 35-mesh stainless-steel Ton-Cap screen in a closed grinding circuit has a life equivalent to 50,000 tons. Table 7 shows standard sizes and numbers.

Ty-Rod screen. The rectangular openings are still further elongated, to as much as 25 times their width. Longitudinal wires, spaced as in Table 7*a*, are tied at regular intervals by groups of three cross wires (Fig. 7, *b*); the screen is fabricated with long dimension of aperture parallel with or normal to length of cloth. Table 7*a* gives data on standard sizes.

Table 7*a*. Specifications of Ty-Rod screens (*W. S. Tyler Co.*)

Choice of woven-wire screen compromises sharpness of separation with capacity and freedom from blinding. Square apertures give the sharpest separation, but they lose more in effective aperture and capacity from inclination. Rectangular screen with a relatively small ratio of length to width increases capacity with but little sacrifice of sharpness with rounded grains and is principally used for such material in the size range from $^1/_2$-in. to 65-m. An increased capacity of 30 to 40% can be expected with such material by use of rectangular openings. The advantage of the rectangular mesh largely disappears at apertures above $^1/_2$-in. Square mesh should be used for slabby material. Rectangular mesh with a large length-width ratio is desirable for finger- or needlelike grains or where moisture or clay tend to cause blinding.

Rectangular-mesh cloth is usually set crosswise in order to give greater metal cross-section in line with the usual transverse stretch on vibrating screens, but it is set longitudinally when blinding is for any reason excessive.

W. S. Tyler Co. reports that when screening clayey gravel on $^3/_{16}$-in. aperture Ty-Rod screen blinded when set transversely and that a 6×14-ft. screen, $^3/_{16}$-in. aperture, failed to handle 600 tons per hr. The work was improved by turning the screen cloth, but then the cloth broke at 800 r.p.m. over the

6-ft. span. Finally, by substituting $1/8 \times 1/2$-in. soft-steel strip for the center shoot wire, life was increased from 1 week to 1 or 2 mo.

Sectional coverings. When the structure of the screening apparatus permits, it is wise to divide the covering into sections. This permits choosing heavier wire for the head section, which both increases the period between changes and distributes the load.

Punched-metal screens are available in plain and alloy steels (also various nonferrous metals and alloys) punched in the following manners (Fig. 8): (*1*) round, staggered; (*a*); (*2*) square, straight rows (*b*), staggered rows (*c*); (*3*) slotted, hit-and-miss sideways (*d*),

a Maximum thickness; gage numbers are U. S. Std.
b Obtainable at any wider spacing, with corresponding increase in permissible thickness of plate.
c Round-hole perforations are obtainable up to 8 1/2 in.

hit-and-miss endways (*e*), diagonal (*f*, *g*), straight parallel rows (*h*), all full-open or burred. Punched metal has the following advantages as compared with woven wire: more evenly distributed wear, hence longer life; less tendency to blind, owing to sharp edges and downward diverging walls of the aperture; on vibrating screens, the smoother surface permits a reduction in the slope (and headroom) required to discharge oversize at a given rate, or on horizontal shaking screens it accelerates the rate of travel; the smooth surface probably also causes less interference with stratification of fine particles in contact with the screen surface, thereby promoting efficiency of separation; in some cases, demanding accurate sizing, the round holes obtainable only in punched metal may be advantageous. Punched metal, however, is limited to apertures 0.75 mm. and coarser for round or square holes: clear slotted screens are obtainable down to 0.30-mm. width of opening.

The chief drawback with punched metal heretofore has been its low percentage of open area; this still applies to fine slotted screen, but improved manufacturing methods now produce round- or square-punched sheet with open areas corresponding to those of medium to medium-heavy woven-wire screen with the same apertures and spacings. Table 8 compares the open areas of round- and square-punched sheet made by an American manufacturer; in each case, the bar or bridge between openings is the small-

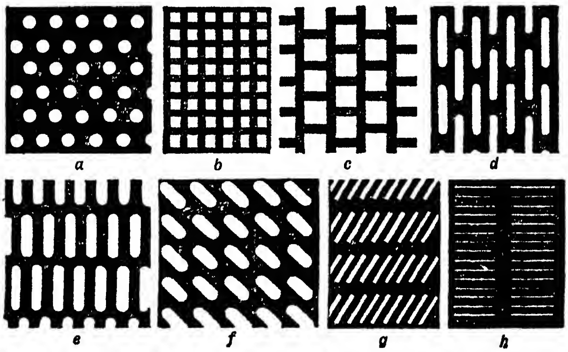

FIG. 8. Types of punched-plate screens.

est of several adopted for that size of hole; gage numbers are U. S. Standard, Table 3. Table 9 gives the British standard specifications for plate punched with round holes staggered at 60°. Table 10 gives standard openings for diagonal-slotted, and Table 11 those for needle-slotted screens of an American manufacturer.

a As usually manufactured in steel.

Lip screen is a form of punched plate with slotted openings diverging in the direction of flow, the plate being bent downward near the lower end of each row of slots to form a drop in the general screen surface. The result is that particles that tend to wedge in the slots are pushed down to the bend and there readily freed. This type of screen is often used for coal screening; it is thought to cause less breakage and abrasion than any other type.

Percentage of open area, punched sheet. The staggering of round holes at the corners of equilateral triangles gives a greater percentage of opening than when holes are at the corners of squares. For diagonal spacing $P = 0.905d^2/(s+d)^2$; for square spacing $P = 0.785d^2/(s+d)^2$, where d = diameter of hole and s = least width of clear metal between holes. With holes 1/2-diameter apart, diagonal spacing gives 40% discharge area against 35% for square spacing; with holes one diameter apart the corresponding percentages are 22.5 and 20. Percentage of opening for hit-and-miss endways punching (Fig. 8*e*) is

$$P = \frac{1}{4}\left[\frac{\pi d^2 + 4d(l-d)}{(s+d)(l+0.866s-0.134d)}\right]$$

where d = width of opening, s = spacing at sides and ends of slots, and l = length of slots. For straight punching and hit-and-miss sideways (Fig. 8*h* and 8*d* respectively) the formula is

$$P = \frac{1}{4}\left[\frac{\pi d^2 + 4d(l-d)}{(s+d)(s+l)}\right]$$

Slotted *vs.* round punched plate. Handy (*94 J 1123*) reports comparative performances on trommels at the BUNKER HILL & SULLIVAN mill. Table 12 shows screen tests of oversize from the two types of covering on trommels taking the same feed. This shows that the 7-mm. slot lets through more undersize than a 10-mm. round hole, thereby working at higher efficiency both in production of <7-mm. material and in producing clean oversize. Table 13 shows that a round-hole plate of a given opening retains 3 to 4 times as much undersize as a slot-punched plate of the same opening. In all of these tests the slots were punched at right angles to the direction of the trommel axis and were of such length that the clear horizontal projection with the plate on a 20° slope was a circle. The slotted screens blinded much less than the round-hole.

Plate *vs.* woven-wire. Data in Table 14, from R. A. Leahy, compare the performances of one Hum-mer (Art. 7) and three Leahy screens (Art. 7) equipped with round-hole punched sheet or woven mesh with square or rectangular openings, applied to coarse, medium, and fine screening in the Tri-State district, where service on wet chert is notoriously severe; in all cases, the screens were in closed circuits with rolls. Failure of woven screens was frequently caused by attrition at the wire crossings, aggravated by the

gritty fines. Sheets showed a tendency to break if too much tension (more than about one-half that appropriate for woven wire) was applied; when plate of No. 8 gage or heavier could be used, the knife-edged clamping bar of the Leahy screen could be omitted and the plate bolted directly to the suspension bar. Suitable slopes were 29 to 31° for sheet, 36 to 38° for woven-wire screens. CONCLUSIONS: (*1*) Marked economy in use of punched sheet is due to lower initial cost and (except for the finest Ton-Cap screen) longer life; advantage of sheet is still more pronounced if cost of replacement labor is considered.

Table 13. Comparative performances of slotted and round-hole plate on trommels (*After Handy*)

Through last screen	10.4	35.1	2.3	10.8

(*2*) Larger percentage of open area in woven wire does not afford a proportionate increase in hourly capacity; probably owing to the smoother flow over the sheet. (*3*) In the case of Ton-Cap No. 451, the orientation of the rectangular openings has little effect on capacity or life. (*4*) The reduction in slope (and headroom) permissible with sheet may often be advantageous. (*5*) Blinding is less serious with punched plate than with woven wire. It should be noted that these conclusions are based on tests with vibrating screens alone.

a Cost for material only; does not include replacement labor.
b Long dimension of hole parallel with flow.
c Long dimension of hole across flow.
d Failed by shearing when about half worn.

Percentage of opening, punched *vs.* woven screen. Consideration of the data in Tables 4, 5, 6, 8, 9, and 10 permits the following general conclusions. In the 3-in. size there is little to choose between the several types of equal weight. From 2-in. to 0.5-in., inclusive, there is considerable difference in favor of plate, as compared to square-mesh wire, the slot-punching giving the greatest opening, but in the 0.75-in. and 0.5-in. sizes the heavy rectangular-mesh has as much open space as the slot-punched plate. From 0.25-in. to 0.10-in., inclusive, slot-punched plate and heavy rectangular-mesh wire screen have substantially equal and the greatest amount of opening, with round-punched plate intermediate and heavy square-mesh wire the least. In the finer sizes, for screens of equal weight, rectangular-mesh woven wire has the greatest opening, needle-slot plate is intermediate, and square-mesh wire screen has the least, except in the finest sizes. Throughout the range of sizes, slotted screens have a greater percentage of opening than square- or round-hole.

Table 15 (*40 MEW 595*) shows the effect on screening capacity of difference in percentage of opening in screens of the same aperture. This test was made with different screens on a 5-stamp battery, the drop of stamps and water flow being maintained constant in the three cases.

Protection of screen surfaces is necessary when heavy loads are put over relatively fine screens. Thus when large run-of-mine rock is to be sent to a vibrating screen of, say, 3 or 4-in. aperture, it is customary to use a 2-deck screen with a grizzly having, say, 6-in. spacing as the upper deck. Another form of protection in a similar case is to weld longitudinal skid bars, 2 or 3 in. high and suitably spaced, on top of the screening surface. This obviates the necessity for a second deck.

Fine cloth, *e.g.*, 48-m. and finer, is usually backed with heavier coarse cloth. Thus at INTERNATIONAL NICKEL 65-m. screen used to close the grinding circuit (Sec. 5, Art. 12) was backed with 4-m. cloth, 0.045-in. diam. wire. Sponge-rubber blanket with large (1 3/8-in.) aperture between the two screens saves wear.

Table 15. Effect of percentage of opening on screen capacity and product

Mesh	24	30	40
Aperture	0.0176	0.0173	0.0178
Percentage on 100-m., 0.005-in. aperture	34.7	36.3	40.2
Tons crushed per 24 hr., by 5 stamps	10.8	14.6	16.4

Size of the product of a screen is by no means equal to the nominal dimension of the opening through which the product has passed. The maximum possible cubical particle that can be passed through a circular opening of diameter d has an edge $0.71d$. Larger platy or rounded particles can pass. Roessler has shown that on several different kinds of materials the average maximum size of the particles passing a round hole is only 81% that of those passing the same size of square hole. When a screen is tilted, the effective aperture is reduced substantially to that of the horizontal projection of the inner edges of the actual aperture. The amount of reduction in effective aperture depends upon the amount of tilt and the thickness of the screen.

Table 16. Equivalent round and square screen apertures, inches (*Recommended by U. S. Dept. of Commerce*)

Square	Round	Square	Round	Square	Round
4	4 3/4	2 1/8	2 1/2	3/4	7/8
3 3/4	4 1/2	2	2 3/8	5/8	3/4
3 1/2	4 1/4	1 7/8	2 1/4	1/2	5/8
3 5/16	4	1 3/4	2	3/8	1/2
3 1/8	3 3/4	1 1/2	1 3/4	5/16	3/8
3	3 1/2	1 1/4	1 1/2	1/4	5/16
2 3/4	3 1/4	1 1/8	1 3/8	3/16	1/4
2 1/2	3	1	1 1/4	5/32	3/16
2 1/4	2 3/4	7/8	1	3/32	1/8

Table 16 gives recommendations of the U. S. Dept. of Commerce on the equivalence of round and square holes for screening of coarse aggregates. Designers with the ALLIS-CHALMERS MFG. CO. estimate that, for a given maximum size of product, the side of a square opening should be 80 to 85% of the diameter of the required round hole; with rectangular-mesh woven wire, the short dimension should be 65 to 70% of the round-hole diameter. Much depends on the thickness of wire or plate; the greater the thickness the larger the aperture necessary to pass a product with a given maximum size.

Arthur Crowfoot (*PC*) states that at No. 6 Concentrator, MORENCI BRANCH, PHELPS-DODGE CORPORATION, a 0.280-in. aperture is used to produce a 0.185-in. product on Hum-mer screens set at 38° from the horizontal. Holbrook and Fraser (*Bul 234 USBM*) state that 1/4-in. screen at 45° made a 1/8-in.

Table 17. Relation between screen aperture and size of largest particle in product of various types of screens

Size of particle, inches *a*	Size of aperture

4	5.75	7.50	7.25	4.75	6.0	6.0

a Intermediate dimension of roughly three-dimensional particles. *b* 40° to 45°.

product, and that at 35° slope round-hole screens pass a product whose maximum-sized particles are about two-thirds the diameter of the hole. Referring to concentrating practice, they say that in one mill a 30-m. wire cloth at 45° gave 50-m. maximum undersize and that a 1-in. round-hole plate at 45° produced $<^1/_2$-in. undersize. Under such conditions, however, the undersize will contain TRAMP OVERSIZE, *i.e.*, occasional particles considerably larger than the average maximum, that work through because of some irregularity in the direction or velocity of presentation. A rectangular-mesh woven-wire screen, with apertures at least twice as long as wide, and set with the long dimension of the aperture parallel to the direction of slope, presents substantially the full aperture to material flowing down slope. On a vibrating screen with fairly large throw, thus equipped, and with material varying considerably in size, the amount of tramp oversize rarely reaches 5%. Bland (*107 J 1114*) states that while 20-m. cloth on some vibrating screens delivers <40-m. product, the screening is incomplete, difficult grains are not passed, and while the oversize from hand screening will be shown to contain 40-m. grains the undersize will contain 20-m. grains. He states further that an inclination of 35° will decrease the effective dimension of the opening less than 10% rather than upward of 18% as would be indicated by the geometrical solution. Table 17 is an empirical table, showing the sizes of maximum particles that are to be expected in a product screened through apertures of various diameters. In the smaller sizes particularly it is necessary to increase the screen apertures as much as 100%, if the ore is damp and sticky, in order to pass the same maximum-size particles.

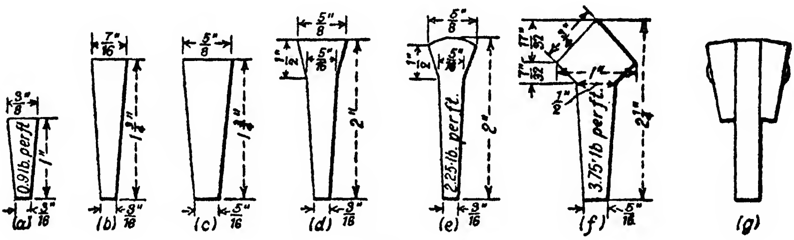

FIG. 9. Grizzly bars.

Bar-screen surfaces are often improvised from discarded rails (flanges up), gravity-stamp stems, or other suitably shaped rolled steel or castings, fixed in parallel position by cross bars and spacers. Better forms are shown in Fig. 9; most durable materials are manganese steel or plain steel with stellited wearing surface. For bars shaped as in Fig. 9 (*a*, *b*, *c*), a taper of $^1/_{16}$ in. on each side per inch of depth will usually prevent blinding by most materials. More recent types of bars taper longitudinally as well as vertically, thus facilitating passage of slightly oversize lumps, the screen, as is usual, being set at a slope permitting the ore to roll or slide. Grizzly screens, which are not intended for close sizing, are usually confined to the coarsest work, as at the head of a mill, although they have been used for separations as small as $^3/_8$ in. Bars are applied to stationary, semiflexible, oscillating, and vibrating screens; for structural details, see Art. 4.

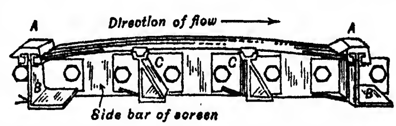

FIG. 10. Longitudinal section of one panel of Rod deck.

Rod deck is composed of spring-steel rods, 23 in. long and of diameters given in Table 18, spaced and held in position (lengthwise of the screen) by being sprung between molded rubber blocks *A*, Fig. 10. The latter are attached to the upper edges of angle bars *B*, forming intermediate cross members of the screen frame. Between end supports, the rods rest on two intervening cross members *C*, also capped with rubber. Any rod can thus be removed or replaced individually; its elasticity holds it securely in place. This method, in effect, produces a screen with apertures about 7 in. long and the widths stated in Table 18.

Table 18. Rod-deck wires and spacings

Opening, in.	Wire diameter	
	W. & M. gage	Inch
$^1/_8$	8	0.162
$^3/_{16}$	6	0.192
$^1/_4$	3	0.244
$^5/_{16}$	3	0.244
$^3/_8$	3	0.244
$^1/_2$	0	0.307
$^5/_8$	0	0.307
$^3/_4$	0	0.307

Another form has the rods assembled in 12-in. panels, usually built with the rods transverse to the flow. Such a surface was used, after extensive tests, for the screens in the cone-crusher circuits at Morenci. Since there is no reason to expect differential wear on particular rods, this would seem to be a better arrangement mechanically. To date (1940) assembled rod deck has not been used for less than 4-m. The manufacturer recommends setting it longitudinally for apertures larger than $^3/_4$-in.

Wedge wire screen is composed of parallel wires having the sections shown in Fig. 11 and dimensions given in Table 19. Usual metals are mild, high-carbon, or stainless steels, brass, and phosphor bronze. At intervals of 2.75 in. for the light and standard sections, or of 6 in. for the heavy sections, each wire is bent to a closed loop, the metal then being pressed from the sides to such thickness as will give the desired spacing when the wires are assembled on rods passing crosswise through all the loops. Wider openings, with wires

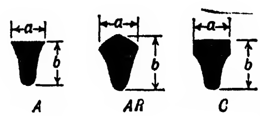

FIG. 11. Sections of Wedge wire.

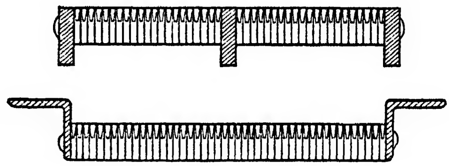

FIG. 12. Methods of mounting Wedge-wire screens.

of a given size, are secured by spacing washers. Ends of the cross rods are either peened or threaded for nuts. Sides of the assembled screen are usually reinforced by plates or angles through which the cross rods also pass, and intermediate longitudinal stiffening bars (about 12 in. apart and supported at both ends) are recommended for screens wider than 20 in. (Fig. 12). For additional rigidity, the loops may be brazed together on their underside and also to the side reinforcements. This method of construction allows the assembling of a screen to any desired dimensions or shape—plane, curved, or bent.

Heller screen is composed of high-carbon (piano) or stainless steel wires, all laid in one direction and attached to a frame only at their ends, with no cross wires. Tension in the wires is sufficient to develop a resonance which facilitates the passage of fines. Standard spacings are $^3/_8$ in. to 150-m. It must not be welded to intermediate supports on account of consequent loss of temper. Screen of this type has been installed on Jeffrey-Traylor vibrators (Art. 7).

TYPES OF SCREENS

Screens are classified on the basis of their method of support as FIXED and MOVING. Fixed screens are placed at any angle from 0° to 45° from the horizontal. When set at the smaller angles they are meant to retain the oversize for treatment such as sledging or hand-picking, and material must be worked over and through them manually. Fixed screens are used for both coarse and fine screening, most frequently in the former service. Moving screens are of many forms, but most of them may be placed in one of the four classes: shaking, vibrating, revolving, traveling-belt. Fixed screens are almost invariably run dry; moving screens are run either wet or dry. Neither type will operate satisfactorily on damp material.

4. GRIZZLIES AND FIXED SCREENS

Fixed screens with heavy screening surfaces usually made of parallel bars, are called GRIZZLIES; Fig. 9 shows typical sections of such bars. Their economical use is limited to coarse screening (aperture 1 1/2-in. and upward). A typical small grizzly as sold by the supply houses is shown in Fig. 13. The bars are usually held together by bolts at right angles to their length and are spaced the desired distance apart by thimbles or sleeves on the bolts. The bolts should be spaced about 2 ft. with heavy, coarse ore, otherwise the bars will spread unless they are very stiff. The disadvantage of this type of screen is clogging owing to the retarding effect of the cross pieces. This may be overcome by making the bars deeper and holding them in comblike cross plates with one through bolt near the head end to keep them in place.

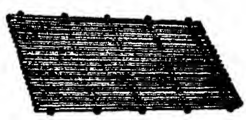

FIG. 13. Standard fixed grizzly.

Fig. 14 shows such an arrangement adopted by the MIAMI COPPER CO. Another form is shown in Fig. 15. Soft steel bars 1 × 5 in. are clipped to heavy 4×4-in. cross supporting angles with heavy angle clips. This method of construction brings the cross bars well below the path of most particles and eliminates interference with the flow of particles. The particular grizzly shown was fed with maximum-size lumps weighing from 100 to 150 lb. and falling approximately 2 ft., yet the bars are said to have been

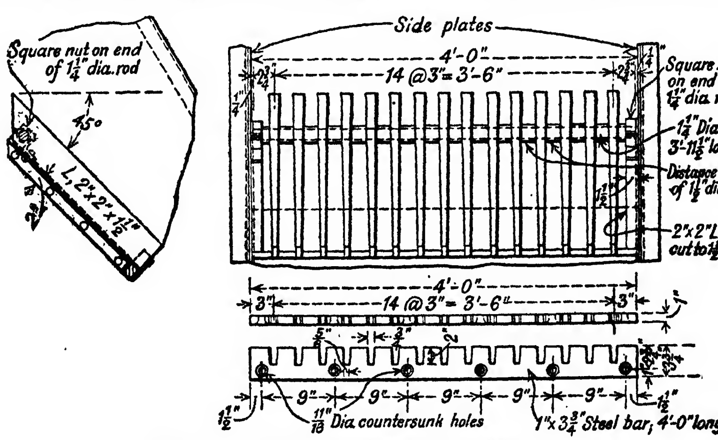

FIG. 14. Tapered grizzly bars with depressed supports.

capable of wearing to 2 in. in height before it was necessary to replace them (*98 J 1045*). Bars that taper along the run as shown in Fig. 14 tend to prevent clogging. At HOLLINGER MINES (*119 Bul CMI 341*) the spaces between bars are enlarged from 3.5 in. to 7.5 in. in a length of 8.5 ft.

Rail grizzlies are widely used for very coarse sizing where severe service is anticipated. These may be made of 15 to 150-lb. rail suitably braced and spaced. They are rarely used with spacings of less than 5 in. because they clog seriously with the narrower openings.

Where the largest lumps in the feed are very much larger than the final size it is desired to pass through the grizzly, the arrangement employed in the QUINCY rock house (*100 J 103*) is useful. Skips dumped onto plates and the rock passed thence first over a short grizzly with 3-in. openings, then over a grizzly (in the same plane) with 6-in. round bars spaced 20-in. centers for taking out the largest lumps

of feed. These passed to a drop hammer. The oversize of the 3-in. grizzly passed to the crushers and undersize to the stamp-rock bins. It was probably necessary to help some large lumps across the coarse grizzly, which was long (12 ft.) and set at 16° slope.

When heavy loads are to be dumped directly onto a grizzly, strength is an important factor in design.

At the Arthur mill of UTAH COPPER Co. (*118 P 469*) 50 to 80-ton cars are dumped by a revolving car dumper directly onto a grizzly set at 35°. The bars are made of 12-in. @ 28.5-lb. I-beams, 32 ft. long, capped with special manganese-steel castings, set with 5-in. clear opening at the upper end and 6-in. at the lower. At ALASKA-GASTINEAU (*63 A 493*) 10-ton cars were dumped four-at-a-time onto plates and thence passed over a 10-in. grizzly made of 8-in. I-beams with manganese-steel shoes. After 6,000,000 tons had passed over this grizzly some of the bars had to be replaced on account of bending but the shoes were still serviceable.

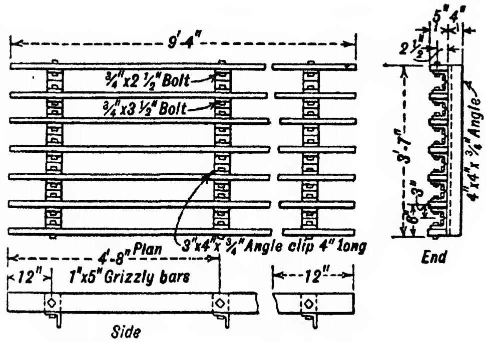

FIG. 15. Grizzly with depressed cross bars.

Slope of grizzly depends upon its purpose. A flat grizzly is used on top of ore bins fed by skips or cars in order to catch and hold lumps that are too large to pass the bin gates or enter the crusher until they can be sledged to proper size, as determined by the spacing of the grizzly bars. Grizzlies in the feed chute to primary crushers are set at such a slope that material will just slide over them (±30°) or will just not slide (±25°) so that the movement over them is readily controlled by the crusher tender, allowing him to remove waste of all kinds from the mill feed. To insure free movement of material, the slope should be from 35 to 45° or as high as 50° for sticky ores. A lower slope may be used when material is delivered with an initial velocity in the direction of the slope.

Holbrook and Fraser (*Bul 234 USBM*) offer the following data on sliding angles. Egg-size anthracite (2 5/16 to 3 1/4 in.) will just slide uniformly on glass at 2 1/4 in. per ft., manganese bronze at 2 5/8 in., mild steel at 3 in. and cast iron at 3 1/2 in. per ft. (16° 15′). Slopes for anthracite are less than for bituminous coal, and ores require more slope than either. Dry quartzite ran well on steel plate at 35°. Steel-lined chutes for Lake Superior copper ores are commonly 26° to 30°. Experimental results are given in Table 20. It must be remembered that blinding causes the screen surface to become rough and that steeper slopes than those given in the table must be used to overcome this difficulty. Moist ores require 10 or 15° greater slope than dry. Concavely curved bars have been used in coal-screening grizzlies, where it is desirable to discharge oversize with as low velocity as possible to prevent breakage.

Table 20. Sliding angles of various substances on bright steel (*After Holbrook and Fraser*)

Material	Starting angle (static friction)	Angle on which material continued to run (kinetic friction)	Slopes used in practice
Pennsylvania anthracite:			
Egg size	15° 40′	14° 00′	14° to 16°
Chestnut size	16° 40′	15° 10′	18° to 20°
Southern Illinois coal:			
6-in. lump	21° 50′	20° 40′	22° 30′ chutes.
Run-of-mine	....	....	30° to 35°
Slack	25° 40′	22° 30′	30° to 45°
Oklahoma screenings	24° 00′	22° 30′	30° to 45°
Chestnut size (McAlester seam)	21° 00′	19° 00′	....
East Kentucky egg, 4 × 6 in.	21° 50′	20° 20′	26° 28′ bars.
Bituminous shale	21° 10′	20° 00′	....
Limestone-gangue ores	19° 40′	17° 30′	
Sandstone-gangue ores	22° 30′	19° 40′	30° to 40° for steel.
Hematite (Lake iron ore)	22° 40′	20° 40′	45° for wood.
Missouri galena	19° 20′	17° 20′	

Size of grizzly depends upon the size of feed, percentage of undersize, slope, and aperture. Width is governed by the same rule as that applying to chutes, *viz.*, minimum width

should be at least three times the size of the largest lumps in the feed, if the feed is fairly uniform in size, or twice as wide, if large lumps are rare. The width is usually determined, however, by other factors, such as chute width, width of car or skip supplying the feed, or receiving width of crusher. Length is determined by the amount of screening to be done, *i.e.*, if the aperture is small and the percentage of undersize large, more length must be provided than under reverse conditions. Steep grizzlies should be longer than flat ones. No quantitative rules can be set down. Length is frequently made twice the width, but for no logical reason. If large particles slide along carrying fine material with them, they can be turned over by a drop in the grizzly surface or by dependent swinging bars, chains, ropes or the like placed about halfway along the length. These will, however, slow down the material and hence make it necessary to set the grizzly on a steeper slope than otherwise. Table 21 gives examples from practice.

a Trapezoidal section.
b Cast-iron bars, 6 in. deep, 1 1/2 in. wide at top, 1 in. thick at bottom; resting on cast-iron combs supported by I-beams.
c Rectangular bars curving downward at lower end and cross-braced only at upper and lower ends; wider spacing at bottom.
d Not full capacity.

Average capacity with rigidly fastened bars may be taken as about 125 tons per sq. ft. of surface per 24 hr. with 1-in. opening and proportionately greater with wider apertures.

Cantilever grizzly improves the screening capacity of the older type of fixed-bar screens by: (*a*) use of bars tapering lengthwise as well as vertically; (*b*) omitting all cross bars except two at the top essential for support. The lower two-thirds or more of each bar is thus free to vibrate under impact from dumping of the load; this, together with the diverging space between bars, multiplies the capacity of a rigid and equally spaced grizzly by four or five times, while also performing satisfactorily with wetter material.

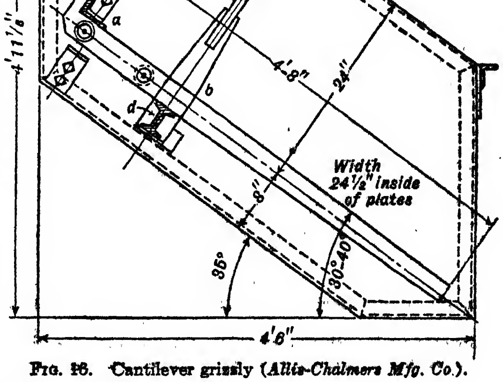

Fig. 16. Cantilever grizzly (*Allis-Chalmers Mfg. Co.*).

Fig. 16 shows one method of supporting the bars adopted by an American manufacturer. From *a* to *b*, the bar is rectangular, 3 × 1 1/8 in.; it tapers thence to the end, where the section is 2 in. high (all the taper being on the underside of the bar), 3/4 in. wide at top, 1/2 in. wide at bottom. Slope of the bars is adjustable between 30° and 40° by two nuts *c*, on which hang the entire weight of screen and load, through the cross bar *d*. Standard sizes range from 2 × 4 1/2 ft. to 3 × 5 1/2 ft., and spacings from 1/2 to 3 1/2 in. Capacity, about 30 tons per hr. per sq. ft. at 1-in. spacing and 35° slope. A similar grizzly was installed

by Miami Copper Co. in the discharge chutes from coarse-ore bins. Here the bars were 4 × 1 1/8 in. for 21 1/2 in. from their upper ends, tapering thence to 3 × 3/4 in. at lower ends; over-all length, 5 1/2 ft. Spacing of 1 in. at top was thus enlarged to 1 3/8 in. at bottom, with a free overhang of 46 in. Two cross bars (3/4-in. round steel with nuts at both ends) were 16 in. apart, upper one being 4 in. from end of bar. With 22 bars, width, c.-c. of outside bars, was 44 5/8 in.

Self-cleaning grizzly. Simcox and Humes (*117 J 307*) describe the grizzly illustrated in Fig. 17. The revolving arms prevent material from sticking between the bars. At Copper Queen smelter this machine handled 196 tons per hr. of talcky ore containing 10 to 12% moisture which could not be handled by other types of grizzlies, and previously had been dried and rehandled at considerable expense.

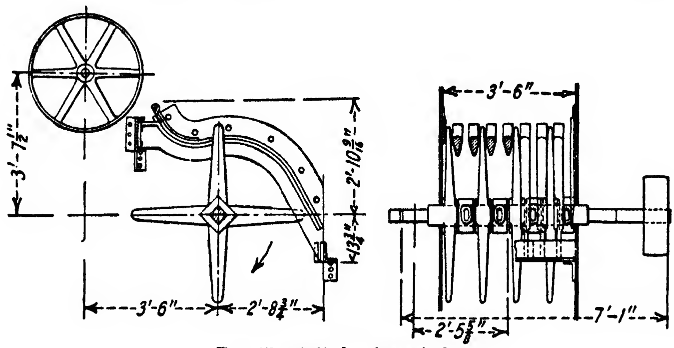

Fig. 17. Self-cleaning grizzly.

Advantages of fixed grizzlies are simplicity and ruggedness. Disadvantages are inefficiency, loss of headroom, blinding, and, in the case of coal screening, breakage of oversize.

Moving grizzlies of various types are used for the purpose of bettering screening, lessening breakage of material, and saving headroom. The first two purposes have determined their use in coal breakers, the second, in many ore-treatment plants.

Moving-bar grizzly (Fig. 18). Bars are mounted at one end on an eccentric, adjacent bars 180° apart, and are so driven that they move forward at the high position. Speed is about 150 r.p.m.; power, 5 to 7.5 hp. The forward movement, together with a forward inclination of about 10°, moves lump material gently along the grizzly and at the same time turns it over well and allows fines to drop through. Usual range of spacing, 3/4 to 3 in.; capacity, 4 tons per hr. per sq. ft. at 1-in. spacing.

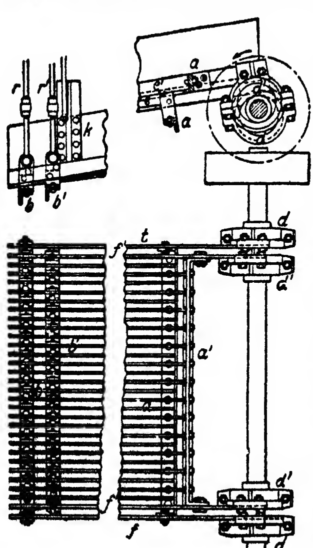

Fig. 18. Briart moving-bar grizzly.

Chain grizzly is suitable for installing between the rails of RR. track over crude-ore bins dealing with large tonnages (500 to 1,000 tons per hr.). At the Rowe Mine, Riverton, Minn. (*101 J 599*), such a grizzly was built of old steam-shovel chains stretched endless over sprockets, the run of the chains being horizontal. Longitudinal rods in the plane of the upper chains were placed between the chains so that the distance of a chain from a rod determined the aperture of the grizzly. Alternate chains were run at different speeds in order to break up lumps held together by clay and to prevent blinding. Oversize traveled on the chains to a chute feeding a primary crusher. The speed of the chains was 16 and 18 ft. per min. respectively, and it was possible to dump a 50-ton car directly onto the grizzly. Eleven supporting rollers were used between the head and tail rollers in a length of about 20 ft.

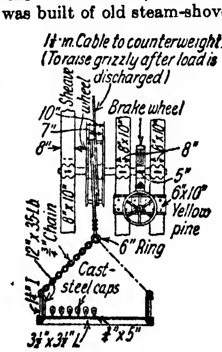

Fig. 19. Movable sorting grizzly, Port Henry Iron Ore Co.

Movable sorting grizzly used at Port Henry Iron Ore Co. is shown in Fig. 19 (*88 J 884*). Its position is controlled by the band wheel. The counterweight is heavy enough to raise the empty grizzly to

a horizontal position. The size is 6 ft. wide and 11 ft. long with 4-in. clear space between bars. The slope for discharging is 35°.

Traveling grizzly (Fig. 20) consists of short lengths of rail running across between two sprocket chains, the latter operating over head and tail sprockets, gear-driven. This grizzly is placed directly under a feed chute and is normally of adjustable speed to regulate feed to a crushing machine. Undersize passes through the upper run and is diverted both sides by chutes. Oversize is discharged over the head sprocket. Any material that tends to wedge between the bars is readily freed at the head sprocket because of spreading of the bars in passing around. Another form of this same grizzly is shown in Fig. 21*a*. The drop of the bars on the lower run clears the surface and also allows the undersize chute to be placed below the return run. Fig. 21*b* shows the same type of grizzly used as a roller feeder. Speeds range, usually, between 10 and 20 ft. per min.

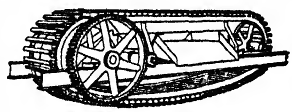

FIG. 20. Traveling-bar grizzly.

Disk or roller type of grizzly consists of a series of disks properly spaced and mounted rigidly on a shaft, usually at the discharge gate of a bin. The shaft is driven by a sprocket chain or by ratchet and pawl; oversize rides on the disks and passes to a crushing machine, while undersize drops between the disks into a chute. Peripheral speed controls the feed rate, but should not, in general, exceed 100 ft. per min.

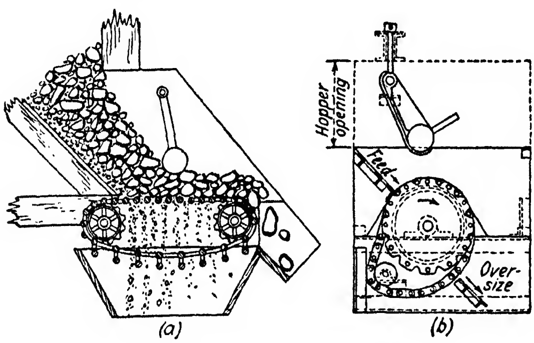

FIG. 21. Drop-bar traveling grizzly.

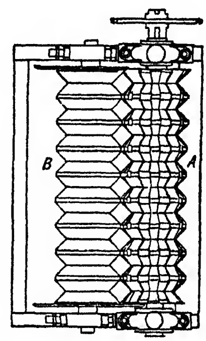

FIG. 22. Ross roll grizzly.

Ross roll grizzly (*45 MM 169*) consists of a pair of rollers corrugated circumferentially as in Fig. 22. Roller *A* only is driven; idle roller *B* is adjustable sideways with respect to *A*. The corrugations of roller *A* are serrated. Feed is onto the idler roll; oversize is carried away over the serrated roll.

Live-roll or spool grizzly (Fig. 23) consists of 5 or a greater odd number of parallel circumferentially grooved rollers *a*, mounted on a frame *b*, which is usually set on a slope of 22 1/2°. Roll shafts project into box *c*, there carrying sprockets *d* of such size and so connected that the rolls are all driven in one direction (upper surfaces down slope) by the drive shaft *e*. Roller speeds increase toward the discharge end, which tends to spread out oversize. Grooving of the roll faces is effected by using cast rollers, or replaceable spools or alternate disk-and-sleeve construction. Aperture is determined by shaft spacing (10 to 18 in. is usual) and disk projection; usual aperture range is 1 1/2 to 7 in. Standard widths are 30, 36, 42, and 48 in.

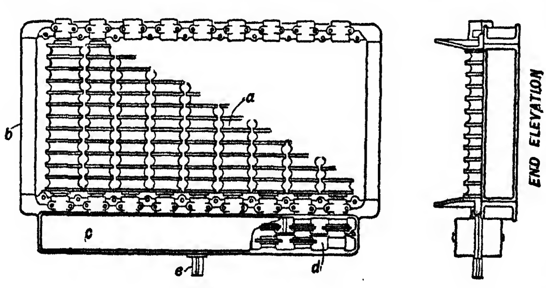

FIG. 23. Live-roll grizzly.

Burch ring grizzly (Fig. 24) is a special form of the roller type. It consists of two disk-shaped heads A mounted on shaft E and tied together by rods G on which are mounted close-fitting rings C, held in place by spacers D, and alternate loose rings B spaced centrally between the rings C by the lugs I. The principle lies in the fact that the loose rings always hang down in such a way that the space between adjacent rings at the bottom is greater than at the top and anything that passes between rings at the top is, therefore, readily discharged at the bottom.

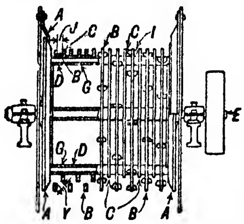

FIG. 24. Burch ring grizzly.

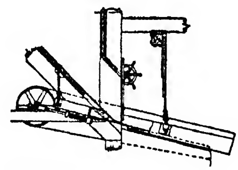

FIG. 25. Shaking grizzly.

Shaking grizzly is shown in Fig. 25. It consists of grizzly bars carried in a suspended frame actuated by an eccentric. The surface of the bars is ordinarily inclined about 10° in the direction of flow, although this is not entirely necessary, if the method of suspension is that of the Ferraris screen. Speed should be about 80 to 100 strokes per min. Capacity is about 125 tons per sq. ft. per 24 hr. per in. of aperture.

At EMPIRE STEEL AND IRON Co. (*99 J 560*) this type of grizzly with 2-in. spaces clogged badly and the bars were replaced by 3/4-in. manganese steel plate with 2-in. round holes. This overcame the difficulty.

Vibrating grizzly, often serving also as feeder to a following crusher, has its bars mounted in a frame which can be vibrated electromagnetically, by the same devices as those applied to the Jeffrey-Traylor "FB" or the Allis-Chalmers "Utah" screens (Art. 7). The bars may be fastened together at their outer ends, or left free, as in the cantilever grizzly. Owing to the rapid vibrations (to 3,600 per min.), and their forward and upward direction, oversize will travel along bars set horizontally or at a very slight pitch, thereby overcoming one of the chief drawbacks of the stationary grizzly.

Fixed screens, as distinguished from fixed grizzlies, are lighter and are used for finer sizing. They have an inclined screening surface consisting of cast-metal grids, punched plate, or woven wire instead of parallel bars. They size more closely than a grizzly since they limit the particle in two directions.

Holbrook and Frazer (*Bul 234 USBM*) report that the undersize of a 1-in. grizzly yielded 24% on a 1-in. round-hole screen and that some of the material would not pass a 2-in. round hole.

Punched-plate screens may ordinarily be set on the same or a slightly steeper slope than a grizzly except that, when used for fine feeds, the slope must be increased. Table 20 gives sliding angles for coal and a few ores on bright steel. Woven-wire cloth must be set on a slope considerably steeper (by 5 to 15°) than either bars or punched plate on account of the rougher surface. Capacity of fixed screens is 2 to 4 tons per sq. ft. per 24 hr. per mm. of aperture.

At OHIO COPPER Co. (*99 J 749*) heavy wire screens, 2 ft. wide by 8 ft. long with 0.375 × 1-in. apertures, set on a 45° slope, handled 250 tons per 24 hr. or 1.1 tons per sq. ft. per 24 hr. per mm. At the old coarse crushing plant of the Arthur mill of UTAH COPPER Co. (*117 P 715*) the 72×20-in. roll circuit was closed with stationary square-mesh woven-wire screens set at 40° slope, the aperture ranging from 1 to 1.5 in. as the moisture ranged from 5 to 13%. In the new plant these screens were replaced by vibrating and later by impact screens. At ALASKA-GASTINEAU (*63 A 493*) <10-in. material was fed at the rate of 1,000 tons per 8 hr. to a stationary woven-wire screen with 2.5-in. aperture, 3 ft. wide by 14 ft. long, set at 45° slope. This is 1.1 tons per sq. ft. per 24 hr. per mm. At TENNESSEE COPPER primary crusher discharge, at 2 1/2 in. and carrying 2.5% moisture, is fed by belt conveyor to a 48×54-in. stationary screen set at 36° slope (*Q*). Rate of feed, 200 tons per hr. The screen is of 0.207-in. Tyloy wire with 1 1/8-in. opening; life, 17 days; replaced by 2 men in 20 min. Blinding does not occur unless moisture becomes abnormal. At ANDES COPPER the 3 1/2-in. primary-crusher discharge passes, on its way to intermediate crushing, over 10 stationary screens fed in parallel by drum or pulley feeders from a 1,590-ton bin (*Q*). Each screen, with an area of 21 × 40 in., consists of two segments of cast-iron plate, 1 in. thick, each segment having 193 cored holes of 1 1/2-in. diam. At average rate of 70 tons per hr. (no circulating load) life of a screen is 12,600 tons; two men replace a screen in 1 hr. Blinding is not serious at normal 4 to 5% moisture. At NEVADA CONSOL. (Ray) 10,000 tons per day of run-of-mine ore passes over two stationary screens in parallel, both discharging undersize to a third stationary screen; all slope 40°; moisture, 3.8% (*Q*). The coarser screens, 10 1/3 × 14 ft. are of manganese steel,

cast in the form of interwoven 1 1/4-in. bars with 3-in. square openings, and in segments 61 × 41 3/4 in. Life is about 5 yr.; it takes 4 men 3 hr. to replace one. Screens are fed through air-operated gates from a 50-ton surge bin. The finer screen, 56 × 80 in., is of woven 1/2-in. steel wire with 1 1/4-in. aperture; its life is 80 days. New Jersey Zinc employs five 32×36-in. stationary screens, all of 3/16-in. steel plate set at 45° slope and all fed, from chutes, with crude ore averaging 1.5% moisture. One with 1.5-in. holes receives 68 tons per hr. of material 26.4% of which is coarser than 1.5-in. round hole; its coarse product carries 40.9% of undersize; life of this screen, 35 days. The other four screens, all having 5/8-in. holes, are fed at rates of 23 to 43 tons per hr. according to their functions in the flowsheet; life averages 50 days.

Rowand screen (Fig. 26) is a modification of the old Edison screen (*OD*). Both types were used by New Jersey Zinc and subsidiaries for relatively fine screening of dry ores. The object of the apparatus is to feed ore in a thin regular stream over the whole screen surface and to break the flow of the ore a sufficient number of times to keep the velocity of the particles on the screen cloth low and to have them, therefore, slide rather than roll and bound. The essential factors in such screening are to have the feed substantially bone dry and to keep the apertures clear. Any moisture decreases efficiency and increases wear markedly. Table 22 gives performances.

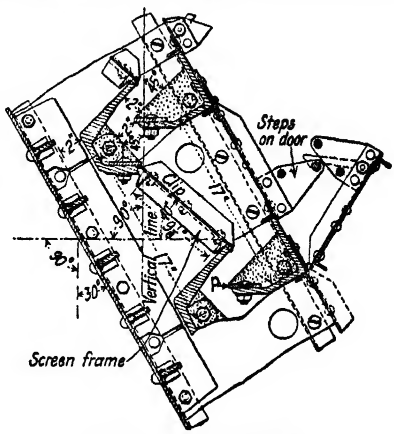

Fig. 26. Rowand screen.

The Rowand screen at New Jersey Zinc was probably the best designed and most carefully operated fixed-screen installation in the world. With bone-dry ore it sized satisfactorily, but at a low rate and an extravagant loss of headroom. With a moisture content so low as to fail to prevent dusting, circulating load built up to enormous proportions, and it required a special mill crew equipped with wire brushes to drive undersize through the meshes. Vibrating screens (Art. 7) are now used.

Table 22. Rowand screens at New Jersey Zinc Co.

[All equipped with slotted steel plates lasting 300 days.]

Drag screen is essentially a flight conveyor (Sec. 18, Art. 9) in a trough with perforated bottom. It may be set at any slope from a downward incline less than the sliding angle of the material to a rise of the same inclination. The usual range in size is from 4 to 10 ft. wide and from 10 to 25 ft. long.

The usual capacity of drag screens with 1/8- to 5/16-in. round-hole plate is 1 ton per sq. ft. per hr.; the general limits are between 2 and 15 tons per sq. ft. per 24 hr. per mm. aperture. The usual speed is 60 to 100 ft. per min. but speeds from 40 to 240 ft. per min. are reported. Wear is not great with coal but is excessive with hard ore. The screen is used principally as a dewatering elevator or conveyor in coal washing, where screening is of secondary importance.

Lincoln (*11 Bul UI, No. 9*) describes such a screen 2 ft. wide × 24 ft. long with 16 ft. of 1 3/4-in. slotted plate and 8 ft. of 3/8-in. square-hole plate which handled 40 tons per hr. of <3 3/4-in. raw coal. Another screen 3 ft. wide × 30 ft. long with 1 1/2-in. grizzly bottom, sloped + 26° for part of the run, then horizontal, handled 600 tons per 8 hr. at 80 ft. per min.

5. REVOLVING SCREENS AND TROMMELS

Revolving screens have been used more widely than any other type of movable screen, but in recent years they have largely been displaced in ore-dressing plants by vibrating

screens (Art. 7). At present the two chief fields for revolving screens (outside of certain small mills where they are retained for their simplicity) are: (*a*) on gold and tin dredges (Sec. 2, Art. 21), for which service they are particularly adapted because of their ability to disintegrate clay-bound or cemented gravel; (*b*) for sizing of construction gravel and crushed stone. Trommels have also entered a new field as "dry scrubbers"; when so used, the screen is equipped with a low, annular dam at its discharge end and, if necessary, plate or angle-iron lifters are fastened inside of the shell. The ordinary cylindrical TROMMEL as used in ore-treatment plants is shown in Fig. 27. It consists essentially of a through-shaft carrying two or more 4- to 6-armed spiders, on the outer end of which circular bands are mounted on which screen cloth is stretched. The main shaft is supported in bearings at the two ends. Several methods of drive are employed. The commonest is the so-called right-angle drive illustrated in the figure, consisting of a bevel gear mounted on the end of the trommel shaft and driven by a bevel pinion on the countershaft, the latter being driven by pulley and belt or, for dry screening, where dust may prevent efficient belt drive, by sprocket and chain. Common diameters for trommels are 24, 30, 36, 42, 48, and 60 in.; lengths, 4 to 12 ft.

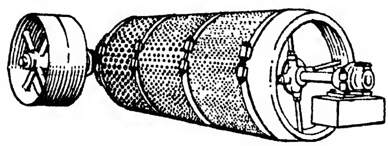

FIG. 27. Cylindrical trommel.

Split spider hubs are superior to solid. The shaft for a 24×72-in. trommel should be 2 11/16 in., increasing to about 4 7/16 in. for the 48×72-in. size. For longer screens the shaft diameter must be increased considerably. The driving shaft should be fitted with a tight-and-loose pulley. The minimum slope of the undersize chute for wet work should be at least 2 3/4 in. per ft. for 2-mm. screen. The chute should slope at least 45° for dry screening. Wash-water boxes are better than spray pipes unless the water is clean and free from salts. Water should be applied on the upcoming side. Water consumption ranges from 1 to 3.5 gal. per min. per ft. of length, the higher figures generally corresponding to fine screening. WATER CONSUMPTION in terms of tonnage of solid fed to the screen ranges from 18 gal. per ton in coarse screening to 420 per ton in 1-mm. screening.

Wiard states that POWER CONSUMPTION is about 1/4 hp. per 2-ft. length for 48-in. trommels. Holbrook and Fraser give the formula *Hp. = tons per hr./10;* also $Hp. = DL/8$ where D and L are diameter and length in feet, respectively, for a coal-screening trommel, and $Hp. = DL/4$ for stone screens working on rock or ore. For light shaft-type trommels for fine screening in concentrating mills they give $Hp. = DL/12$.

Trommels for wet screening may be set up in banks of two to four in line, with intermediate spur-gear drive, but individual drive is better.

Performances of cylindrical trommels in several mills are given in Table 23.

At WHITE BIRD (*IC 6353*) two 4×8-ft. trommels with 1/2-in. round-hole screen were in closed circuit with rolls; new feed to the circuit was 31.2 tons per hr. from primary crushers. Another 4×8-ft. trommel with 1/8-in. round-hole screen was in closed circuit with rolls recrushing rougher-jig tailing. At MASCOT (*IC 6379*) four 4×8-ft. trommels in parallel, in closed circuit with rolls, received 24.6 tons per hr. each of new feed. Screen covering was 5/8-in. round-hole on the upper half; 1/2-in. on the lower. Slope, 1 1/2 in. per ft.; speed, 15 r.p.m.

Mill trommels. Small screens of trommel type are usually attached to the discharge end of rotary grinding mills when jigs, tables, or unit flotation cells precede the classifiers; also to extract wood chips, tramp iron, etc.

At SUYOC CONSOLIDATED two such screens, 36 × 28-in. and 18 × 20-in., are used on 5×8-ft. ball mills. Covering is 3/32-in. wire, with 1/8-in. aperture; the larger lasts 60 days; smaller, 180 days. Four men spend 3 hr. to replace the larger screen, 2 hr. for the smaller. With interior sprays, undersize from the larger screen carries about 79% solids; from the smaller, about 68%. DENVER SPIRAL SCREEN is designed to improve the efficiency of such an operation. It has a spiral flight composed of a continuous steel strap, on edge, fitting closely inside the screen jacket; this accelerates passage of oversize and thus thins the bed. It is built 12- to 36-in. diam. and 18 to 36 in. long for 2 1/2- to 8-ft. mills.

Compound trommels have two or more concentric screening surfaces on the same shaft, the coarsest inside, the lengths successively less from inside to outside. They are used when several short-range products are desired from one long-range feed and headroom is at a premium.

The DISADVANTAGES are that it is necessary to remove the outer screens in order to make repairs on the inner, it is difficult to watch the inner screens for wear and blinding, and the area of the expensive fine-screen cloth is unnecessarily great.

At NEW IDRIA (*IC 6462*) a combination trommel and disintegrator was used. It was double-jacketed full length (26 ft.), each jacket comprising three sections. The inner, 48-in. diam., consisted of: (*a*) 10 ft. of high-carbon steel plate 1/2 in. thick, with 1-in. round holes; (*b*) 6 ft. of similar plate, without

perforations, but provided with lifting and tumbling baffles; (c) 10 ft. of 3/8-in. plate with 1-in. holes. The outer jacket, in corresponding sections, was composed of: (a) wire screen with 1/2-in. openings: (b) 3/16-in. plate, unperforated; (c) 3/16-in. plate with 9/16-in. holes. Run-of-mine ore (except some >4-in. hand-picked waste) was thus separated into: >1-in. for picking belt, 1 1/2-in. for furnace, <1/2-in. to a classifier yielding coarse for furnace and fines for flotation. Slope was 1 1/4 i.p.f.; speed, 12 r.p.m.

Conical trommels are made with and without a through shaft. The latter type, called the Gilbert screen, has had considerable use, particularly in gravel-washing plants.

The ADVANTAGE of the conical trommel is that the axis may be set horizontally, when the inclination of the screening surface necessary to cause travel of material is obtained by the conical shape. It is also economical of headroom. The open-end type has ample space for feeding through the discharge end, but it is necessary that the feed be carried in suspension in water. Chief DISADVANTAGE is the complicated pattern to which the screen fabric must be cut and fitted.

OLIVER IRON MINING Co. employs a conical trommel 20 ft. long by 8-ft. large and 4-ft. small diam. giving an effective slope of 1.2 i.p.f. Covering is 1-in. steel plate with 2-in. holes. Speed, 12 r.p.m. with e[illegible] of-mi[illegible] wet at 15,600 tons per 24 hr., equivalent to 1.7 tons per sq. ft. per hr., or 0.81 ton per sq. ft. per 24 hr. per mm. of aperture. Water consumption, 32,820 gal. per hr. (O). Fig. 28 illustrates two installations of conical screens in gravel-washing plants. That (A) of the ATLAS SAND, GRAVEL & STONE Co. (*IC 6676*) contains two parallel banks of three screens each, all driven at 20 r.p.m. through gears, sprockets, and roller chains, from a 15-hp. motor. Most of the feed has previously passed a 2 1/4-in. vibrating screen, but some unsized product of a jaw crusher set at 2 1/4 in. is included, and accounts for the oversize product of the 2 1/2-in. round-hole trommel. Total feed to each bank is 33 tons per hr. Water in a 4-in. stream enters with feed, and additional water is applied inside each screen by a spray pipe; total water for three screens, 250 g.p.m. Entire weight of each screen and its load is carried by the cast-iron head at the small end; this is supported on a 4-in. shaft 10 ft. long, and carries four 6×6-in. angles to which the jackets are attached, 6 in. apart. Average life of screen is about 150,000 tons. Plant (B) of the DALLAS GRAVEL Co. (*IC 6581*) has three conical screens all mounted on the same shaft and rotated at 10 r.p.m. by connection, at upper end, with a 50-hp. motor (which also drives the elevating conveyor). Feed has all passed a 6-in. grizzly, and includes recrushed (gyratory) oversize product of the first trommel. Oversizes of the second and third trommels are usually subdivided for market on vibrating screens at 1 1/2, 1 1/4, 1, 1/2, and 5/16 in. Average life: No. 1, 300,000 tons; No. 2, 200,000; No. 3, 75,000.

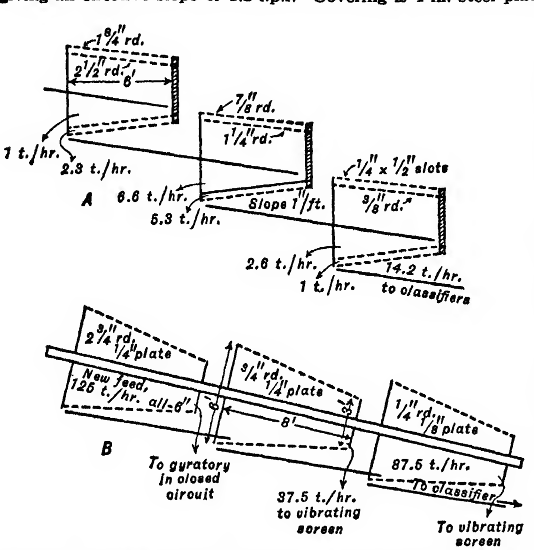

FIG. 28. Arrangements of conical screens for gravel washing.

Prismatic trommels, usually hexagonal, have been used to a considerable extent in fine screening. The sides may have their elements parallel, in which case the axis is set on a slope, or pyramidal with the axis set horizontal. The screening surface consists of a number of plane sections. This makes for ease in mounting and changing screen cloth, as the cloth is mounted on separate wooden frames that bolt onto the main screen frame. Cloth may be shipped flat, is lighter to handle than that for a cylindrical trommel, being in smaller pieces; and the amount of screening surface that need be replaced for a break in the screen is only one-sixth of the total.

Comparison of round and hexagonal trommels for fine screening was made at DESLOGE CONSOLIDATED (*94 J 833*). The feed was undersize of a 10-mm. trommel and it was desired to remove material that would pass a 1-mm. opening. Comparison was between a round trommel of the conical type, 8 ft. long with diameters 3 and 4 ft., slope 3/4 i.p.f., speed 20 r.p.m.; and a hexagonal trommel 8 ft. long, pyramidal shape, large diam. 4 ft., small diam., 3 ft., speed, 20 r.p.m. Pulp in falling from one face of the hexagon to the other dropped 14 in. Screening surface used on both trommels was punched plate, 22-gage steel, 1-mm. round holes on 2.5-mm. centers. Outside spray was used on both. Feed rate,

both trommels, was 150 tons per 24 hr. Duration of the test was several weeks. Results were as follows: Material finer than 1-mm. in oversize; conical trommel, 7.0%; hexagonal trommel, 4.8%. Life of screening surface: conical trommel, 7.1 days, 1,065 tons; hexagonal trommel, 12.8 days, 1,927 tons. The experimenter calls attention to the fact that the difference in life of screening surfaces is due to the fact that the interior rings of the conical trommel caused pulp to back up behind them and that the greater weight of pulp sliding around at these points caused the screens to wear through. The higher efficiency of the hexagonal trommel was due to greater turnover of pulp.

Revolving stone screens, as distinguished from trommels, have no central shaft but are mounted on tires and rollers at both ends, or one end is so mounted while the other end carries a heavy head and gudgeon (Fig. 29*b*). On account of the slope, guide rollers are required, bearing against the low side of one of the tires. This type of screen is used mainly for coarse screening and less frequently in ore-treatment than in stone-crushing plants; but it is practically the only type found on American dredges (Sec. 2, Art. 21). The screen

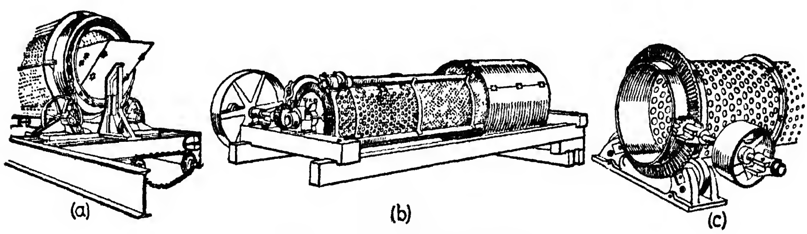

Fig. 29. Revolving stone screens.

frame consists of heavy cast heads with four or more longitudinal members connecting the heads and forming with them a strong truss. The screening surface is attached to the through members. The best arrangement is one in which the screens are in sections, each section bolted in between two adjacent through members as shown in Fig. 29*b*. Commonly stone screens are sectional (Fig. 29*b*), *i.e.*, plate or cloth sections have successively coarser aperture from feed to discharge end. Not infrequently, also, they are compound at one end. Right-angle drive is usual, but some forms are chain-driven by a sprocket bolted to the feed- or discharge-end casting (Fig. 29*a*). The frame is sometimes built to carry a grid of heavy rods on the inside surface, parallel to the axis, with an aperture larger than the coarsest screen. This rides the largest lumps through the screen out of contact with the screening surface and thus protects the latter. Table 24 gives sizes and weights by one manufacturer.

The principal DISADVANTAGE of this type of screen is the fact that all the coarse material must pass over the finest plate, which is thereby subjected to excessive wear. This difficulty may be obviated, although at the expense of headroom, by passing the original feed first to a heavy screen of intermediate size, each product of this screen then going to a separate sectional screen having suitable cloth. The same effect is obtained by compounding, subject to the disadvantages previously mentioned.

Performance. See Table 25. See also Sec. 2, Art. 21.

Until 1931, the screening equipment of the N. Y. Trap Rock Corp., at Clinton Point, included four stone screens with inner walls 4 × 16 ft., 3 1/4-in. round holes, and outer jackets 6 × 16 ft., 2 1/4-in. round holes. Each screen had a 25-hp. motor. Maximum feed rate was 500 tons per hr. Screening efficiency was unsatisfactory (*34 # 9 RP 65*). For results after substitution of Gyrex vibrating screens, see Art. 7.

Variables in construction and operation of revolving screens are speed, slope of screen axis, aperture, percentage of oversize in feed, percentage of moisture in feed, rate of feed, and diameter, length, and character of screening surface.

Speed affects capacity and efficiency. Increase in speed up to the point where material is carried completely around by centrifugal force causes increase in capacity. Efficiency, however, passes through a maximum at a speed which, roughly, causes the load to ride about one-third the distance to top of the screen.

Results of a test on a 36-in. trommel with varying speed (*98 J 305*) are given in Table 26 and Fig. 30, showing, for this size, maximum efficiency at 16 r.p.m. Since efficiency and not capacity is the end sought in most screening operations, this speed, or one slightly greater, is the one that should be and is commonly used in practice for this size of trommel.

Tables 23 and 25 show speeds of revolving screens in operation. Usual speeds range between 35 and 40% of theoretical critical (see Sec. 5, Art. 2).

Slope of a trommel affects the rate of travel through the screen, and for a given tonnage determines the thickness of the bed. This factor in turn influences efficiency, the thinner the bed the greater the opportunity for a particle to gain access to an aperture. Within limits, increase in slope increases efficiency and capacity. Old practice used slopes of 0.5 to 0.75 i.p.f.; present practice averages about

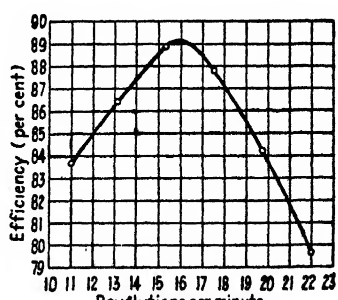

FIG. 30. Relation of trommel speed to efficiency. (Data in Table 26.)

1.5 i.p.f. in ore treatment, with maximum of about 3 i.p.f. According to Holbrook and Fraser, 5° is standard slope for punched-plate trommels in coal treatment and slightly more for woven wire.

Table 26. Relation between speed and efficiency of trommel *a* (*After Roesler*)

a Diameter, 36 in. Length, 12 ft. Slope, 1 1/4 in. per foot. Perforations, 1/2-in. round holes, punched on lines intersecting at 60°. Percentage of opening, 40.3. Rate of feed, 22 to 24 tons per hr. Speed, 11 to 22 r.p.m. (Data plotted in Fig. 30.)

Diameter of a trommel determines the thickness of the bed; the greater the diameter the thinner the bed. It is not advisable to use trommels less than 36 in. diam. on account of the difficulty of changing screens and making other repairs. The majority of trommels range from 36 to 48 in. diam. H. G. Smith (*47 MM 20*) offers the formula: $D = 7.66\sqrt{W/d}$, where D = diam., in.; W = desired capacity, tons per hr.; d = approx. sp. gr. of material, as fed (about 2.0 for most siliceous or carbonate ores).

Length affects efficiency of screening, increased length resulting in more complete removal of fines. On the other hand, most of the screening is done in the first 2 ft. Present practice inclines to steep slopes and short lengths. *Truscott* gives 5 to 15 ft. for one separation, the longer for finer materials, but few trommels exceed 10 ft. Stone screens are longer.

Capacity increases with increase in diameter, speed, slope, and size of aperture, with decrease in percentage of difficult oversize in the feed, and is greater in wet than in dry screening. For dry screening, it averages 0.6 ton per sq. ft. per 24 hr. per mm. of aperture, and for wet screening, 1.0 ton. *Wiard* gives the rule for capacity of 48-in. trommels in open circuit, $C = 20\ d$ for round-hole punched plate and $C = 25\ d$ for square openings, where C = tons per 24 hr., d is the aperture in mm., and the feed contains 50% oversize. With a greater percentage of oversize, capacity will be greater to an extent substantially equal to the tonnage of excess above 50% oversize. Deduct 15% from the above capacities for each 6-in. decrease in trommel diameter. *Truscott's* figure is 0.5 ton per 24 hr. per sq. ft. per mm. of aperture. Holbrook and Fraser give the rule for capacity on coal that 3 to 4 sq. ft. of screen surface is required per ton per hr. per in. of aperture, with an increase of 50% in the area required if the coal is damp.

Efficiency. Average oversize from coarse (>0.5-in.) dry trommels contains about 15% undersize, while that from fine (<0.25-in.) wet trommels contains about 30%. Efficiency reckoned as percentage recovery of undersize may run as high as 80% in 1/2-in. dry trommels. In wet trommels 45 to 70% is the usual range, but the figure may drop to 10% or lower when there is much material in the feed near the size of the screen opening and the trommel is overloaded.

Life of covering on trommels is given in Table 23 and for that on stone screens in Table 25.

Advantages of trommels are simplicity in construction and operation, freedom from vibration, small loss of headroom, cheapness, and general ruggedness. Disadvantages are blinding, difficulty of repair, low capacity per square foot of screen surface, and low efficiency.

6. SHAKING SCREENS

Description. Shaking screen consists essentially of a shallow rectangular box two to four or more times as long as wide, open at one end, fitted with a screen bottom and shaken by means of a suitable mechanism which alone, or in conjunction with the slope of the screen surface, moves oversize to the discharge end. The method of support of the frame and the means of shaking vary considerably. In the oldest and simplest form the frame is

supported on four vertical rods or chains at the corners and is actuated by an ordinary eccentric, producing a substantially straight-line harmonic motion; the screening surface must then be given a slope of 10 to 15° in order to move material, or the forward stroke must be ended against a bumping block, resulting in excessive rack and vibration on the screen frame and supports. By inclining the supporting rods backward from the vertical at an angle of about 15° (FERRARIS SUPPORT), the motion of the screen surface is upward at the end of the forward stroke and sharply downward at the beginning of the backward stroke, with the result that the screen drops away from under the load and the material moves ahead with a series of jumps. This motion is accentuated by shortening the suspending or supporting rods. The same effect, even more sharply accentuated, can be obtained by mounting the screen frame on rollers and shaping the track to give a sharp upward movement at the end of the forward stroke. Occasionally, with track support, the track is also turned up at the end of the backward stroke, in order to give some backward travel of the material and thus increase the length of path and multiply opportunities for undersize to pass. Table head motions which impart a differential, quick-return movement are suitable only for relatively short strokes (1.5 in. or less) and relatively small screens. With mechanisms producing differential movement the screen surface need be inclined only slightly or not at all in the direction of flow. For design and operation of shaking screens in coal preparation, which is now almost the only field for the simple types as above described, see Vol. II.

Speed, slope and length of stroke should be adjusted to produce rapid stratification of the feed, quick forward movement of the load, and minimum blinding. If speed or length of stroke is too great, material is thrown bodily away from the screen surface and stratification is effected slowly, if at all. On the other hand, if there is too little throw, the screen blinds badly. Slope is adjusted so that with a proper speed and length of stroke there is sufficient throw of material away from the screen surface to prevent blinding. Speeds in practice range from about 60 or 70 @ 9-in. strokes per min. to about 800 @ $^3/_4$-in. strokes. If there is any considerable amount of lost motion or backlash in the eccentric or suspending mechanism, the action of material on the screen may be entirely different from that with the same mechanism with no backlash. Suspending rods made of ash boards, 1- by 10- or 12-in. in section, attached rigidly at both ends, are very durable and have a tendency to reduce backlash.

Capacity ranges from 2 to 8 tons per sq. ft. per 24 hr. per mm. of aperture. In desanding pebble phosphate 15 to 20 tons per sq. ft. per 24 hr. per mm. of aperture is sent over $^3/_{64}$-in. screens in a 3-in. bed with 400 to 500 g.p.m. of wash water, but the screening is not efficient. Wiard (*Liddell*) gives a formula that reduces to $T = AR/6P$ as a maximum theoretical tonnage for shaking screens where T = capacity in tons per hr. per ft. of width; A = average between screen aperture and preceding limiting-screen aperture, expressed in feet; R = rate of advance of material over the screen in in. per min. = shakes per min. × amplitude of shake; and P = ratio of weight of oversize to total feed.

Applicability. Shaking screens are used to the greatest extent in coal preparation, where they have substantially displaced all other types, and in treating certain nonmetallic ores such as phosphate and asbestos. They are used both wet and dry, but consume excessive amounts of spray water when used wet. Many attempts have been made to set the screen so that it moves up and down through the surface of a body of water, but this involves mechanical removal of undersize, which has not proved successful. Shaking screens are not suitable for treating clayey ores on account of the readiness with which clay balls form on them.

The principal DISADVANTAGE of shaking screens is the high repair cost due to rack and vibration. This applies not only to the screen itself but to the supporting structure. In order to minimize the effect on the structure two screens are frequently mounted on opposite sides of the same drive shaft with eccentrics at 180°. Even this is insufficient, however, to balance the load because of the difference to be expected in load of material on the two screens at any given instant; hence many designers make the shaking-screen support independent of the building frame, in order to localize vibration and not rack the entire building. Lubrication is difficult.

Symons horizontal screen employs the Ferraris principle of inclined, flexible supports, with modifications designed to reduce unbalanced vibration. The horizontal screen box is supported, at four places on each side, by springs composed of two or four thin steel blades, the four-blade springs being at the ends of the box. All springs are rigidly fastened at both ends, to the screen box above and to a foundation frame below, and all lean, at 30° from vertical, toward the feed end. The resultant motion of the screen surface, upward on the forward stroke, thus causes the feed to travel toward the discharge end. Motion is supplied by a rotating, horizontal shaft across and beyond the discharge end, having two eccentric shoulders; the collars on the eccentrics are flexibly connected (by horizontal blade springs) to the screen box. The main bearings on the outer ends of the shaft rest upon the ends of two long horizontal bars parallel with and outside of the screen box and supported on inclined blade springs in

exactly the same manner on the screen box; the other ends of these bars carry a feed box. Vibration induced by the eccentric rotation is thus divided between the screen box and the outside bars and is practically neutralized. Single- and double-deck screens are 36, 42, and 48 in. wide by 6, 8, 10, 12, 14, 16, 18, and 20 ft. long; triple-deck (same widths), 8, 10, and 12 ft. long; a single-deck 24 in. × 6 or 8 ft. is also available. Over-all length (incl. motor) is about 53 in. plus screen length; over-all width, 23 to 26 in. plus screen width; height of feed box above floor, 40 to 43 in. for single- and double-, and 52 in. for triple-deck screens. For performance see Table 27.

Cole screen has a slightly sloping deck supported on four inclined legs (Ferraris principle) and oscillated by two pitmans driven from eccentrics, thus producing an upward movement on the forward stroke. Legs and pitmans are all attached to the screen frame through flexible rubber wrists. Such a screen at CANANEA (*IC 6261*), with 44 × 49 in. of double-crimped cloth (1/4-in. wire, 1-in. opening) received 2,600 tons per day of product from a gyratory crusher set at 3 1/2-in. max.; speed, 430 s.p.m. Table 28 gives sizing analyses of feed and products, showing 25% of undersize remaining in oversize.

VIBRATING SCREENS

In recent years, vibrating screens have largely displaced trommels and shaking screens, owing chiefly to their larger capacity per unit of screen area and floor space and lower cost of operation and upkeep per ton screened. Their field ranges from 10-in. to 100-m. aperture, wet or dry; in the finer sizes thay have been substituted at several mills for mechanical classifiers, and in coarse sizes for grizzlies. In industrial screening they have been used down to 200-m. wet and 325-m. dry, but even the manufacturer concedes that air classifiers (Sec. 9) are superior in the latter field. As substitutes for grizzlies they save headroom and floor space, make a cleaner cut, blind less, and serve also to equalize rushes of feed to a certain extent. The modern eccentric-drive machines, with rubber-floated bearings to cushion the shocks caused by unbalancing from heavy fluctuating live loads, can handle feed lumps of several hundred pounds by using protective grids (see p. 31). See the different types for their special size fields.

Vibrating screen consists essentially of a substantially plane screening surface, usually stretched taut, more or less inclined, and caused to vibrate with small amplitude and comparatively high frequency. The screening surfaces, single up to 4-deck, are set as diaphragms in a rectangular frame having suitable side walls to confine flow (screen box). **Sizes, which are stated as deck dimensions, range from 1 1/2 × 3 ft. to 6 × 16 ft.**

Types. Vibrating screens are available under a bewildering variety of trade names. Fundamentally, however, there are only two types, (*a*) those in which points in the screening surface reciprocate over substantially rectilinear paths, and (*b*) those in which the paths are closed, either nearly circular or pronouncedly elliptical in general outline. In both types the path lies in a plane or substantially plane surface parallel to the side walls of the screen box. Motion along the paths is nonuniform in most cases; in the impact types reversal is sudden.

Vibrating mechanisms are electrical or mechanical; their impulses are applied directly to the screening surface, or, in most cases, to the screen box. Electrical mechanisms are all a.-c. electromagnets, with or without mechanical expedients such as stops or interposed resilient elements to amplify and/or intensify the vibrational effects. Mechanical methods comprise hammers, cams, eccentrics, gyrators, and various combinations of these mechanisms. More detailed descriptions follow in connection with specific machines.

Impulse and restraint. The force applied to the particles on a vibrating screen is a resultant of the impulse of the mechanism on the screening surface or the frame, the restraints opposed to this impulse by the screen structure, and the further restraints imposed by gravity acting on the screen structure and on the material on the screening surface. The magnitude of the initial impulses depends upon the power supplied and the way in which it is converted to force at the points of application. The impulse on the screening surface depends upon the type and strength of the constraints to motion brought into play between the point of application of the applied force and the screening surface.

Intensity of vibration is a function of length of path and rapidity of reversal. Ordinarily it is expressed simply as the product of the length of projected path at right angles to the screen frame and the frequency, which is to say, the cumulative linear travel in one direction at right angles to the screen surface per unit of time. Thus a screen surface making 1,000 v.p.m. along a circular path $^1/_{16}$ in. diam. would be said to have an intensity of 62.5 (in. per min.). But the actual intensity of such vibration, assuming uniform motion along the path, would be greater if the path were elliptical, with $^1/_{16}$ in. the major axis, and at right angles to the screen surface, and the relative increase would be greater the larger the ratio of major to minor axis of the ellipse. The intensity would be much greater with a linear path of the same projected length if there were any substantial approach to uniform motion along the path; and it becomes a maximum when a linear path is stopped by a sudden impact. No method has been devised for numerical quantification of the intensification due to rapid reversal.

Particle movement on and over the screening surface is the resultant of gravity and the force exerted on the particles by the surface. With most screens gravity is the primary force and the screen surface is inclined to such an extent (20 to 40°) that a very slight impulse from the surface is sufficient to make the particle progress down slope. The ideals in particle movement are rapid translation, which makes for high capacity; continuous contact with the surface, which insures repeated presentation to openings; turnover, which causes ever changing orientation of the presented particles; and ejection, or outthrowing of particles incapable of passage through an aperture, in order to give other particles access to that aperture and to give the ejected particle opportunity to present itself differently to another aperture.

Rapid translation is obtained by steep slope and/or high intensity of vibration. Speed should not, however, be so high as to cause the load to bound across the surface, since such progression defeats the other purposes of particle movement by preventing access to apertures.

Continuous contact is attained by decreasing the slope and by increasing the load passing over the surface. The decreased slope of itself decreases the length of screen surface passed over in one bound caused by an impulse of a given intensity, and the increase in load reduces the freedom of particles to respond to impulses by leaving the surface.

Turnover is effected to a certain extent by opposition of the rough surface of the screen fabric to the forward flow of particles in contact with it. It is accentuated, however, with closed-path motion, by having the upper portion of the vibratory path directed toward the feed end of the screen (COUNTERFLOW).

Ejection is best effected by impact at the end of the upward stroke. Failing this, it is probably next-best attained by an acutely elliptical path with as nearly as possible uniform motion along the path.

7. OPEN-PATH (RECIPROCATING) VIBRATORS

These were the earliest type, representing the first departure from trommels. The pioneer forms comprised mechanical hammers applied to fixed inclined screens. An a.-c.

magnetic hammer was used on Rowand screens (p. 27). In the early impact screens the screen frame, with inclined screening surface, was lifted by cams and dropped. Modern forms utilize either mechanical or electrical means for the primary impulse and may additionally make use of gravity or the restoring force of a spring for return.

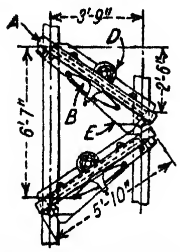

Fig. 31. Colorado impact screen.

Mechanical Impact Types

Colorado impact screen (Fig. 31) consists essentially of the frame *A* which carries the screen cloth and an undersize hopper *E*, mounted on two elliptical wagon springs *B* which are fastened to the supporting frame. A pulley-driven shaft carrying multiple-armed cams *D* is also mounted on the supporting framework. Revolution of the cam depresses the screen frame, which, on release, springs forward against bumping blocks on the framework. The usual speed is about 600 knocks per min. The screen surface is set at a slope of about 40° from the horizontal. Screens may be superimposed, as shown in Fig. 31. Average capacity per square foot of screen surface per 24 hr. at 1-mm. aperture is about 5.5 tons for dry screening and about 20 tons for wet screening. An efficiency test on impact screens at Ray Cons. Copper Co. is shown in Table 29.

A modified (Duckworth) type of Colorado impact screen is employed in both mills of the Utah Copper Co. Ay Magma it receives the undersize of a 2-in. grizzly following the primary gyratory crusher; at Arthur it is used in the same way, and also in closed circuit with rolls for intermediate wet crushing. Table 30 gives operating data.

Leahy-No-blind screen is vibrated by impacts applied to a cross bar at its mid-length. Fig. 32 is a cross-section of the vibrating mechanism, which is mounted on a bridge spanning the top of the screen box. The 8-pointed cam *a* is keyed to the shaft *b*, which rotates usually at 200 r.p.m., giving 1,600 v.p.m. The cam engages a hardened-steel button under the inner end of the tappet *c*, the outer end of which presses on the upper end of rod *d*. The lower end of this rod (not shown) is attached by a yoke to the cross bar of the screen. The rod is forced upward by the helical compression spring *e*, stress in which is adjusted by nut *f*. With perforated plate, spring compression need be only about one-half of that desirable with woven-wire screen. The profile of the cam is such that the down stroke occupies 81.4% of the tappet cycle; the upstroke ends with a knock which, together with the quick upstroke, activates the screen load and tends to prevent blinding. Usual amplitude of vibration is 1/8 in.

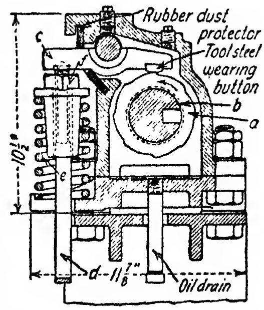

FIG. 32. Vibrator for Leahy screen.

The cam runs in oil, and its shaft may be driven by belt and pulley from a countershaft or by direct-connected motor mounted on the bridge; power consumed is about 1/2 hp. The screen box is hinged at its lower end and its tilt, usually 28 to 35°, is adjustable by a pair of ratchet bars and pinions supporting the high end. The longer screens usually have two vibrators connected by sprocket chain. In the TRI-VIBE model there are three vibrating cross bars, at the quarter-points, connected both ends by longitudinal side bars; impact is applied only to the middle bar and is transmitted to the others by the side bars.

Performances. A 3×5-ft. screen at the RICHARD MILL, with 0.194-in. square aperture, at 35° slope, and 200 r.p.m. handled 28 tons of magnetite ore per hr. through 3/4-in. round-hole plate, with 3 to 5% moisture, at an efficiency of 92%. With less than 1% moisture the efficiency rose to 98.5%. At IRON MOUNTAIN, a similar screen handled 19 tons per hr. of wet hematite ore with an efficiency of 99.6% and was underloaded. H. M. Roche (*PC*) believes that the screen could have handled 38 to 40

tons per hr. with 98% efficiency. These performances indicate a capacity of 9 to 12 tons per sq. ft. per 24 hr. per mm. of aperture. At FLAT RIVER (*IC 6658*) 12 Leahy dry screens were in closed circuit with rolls, and 12 wet screens in closed circuit with a rod mill (the latter screens have since been replaced by drag classifiers). Table 31 gives data on the screens of both groups. At BONNE TERRE (*138 J 286*) one double-deck Leahy screen receives the product of a primary gyratory crusher fed direct from mine skip and set to deliver at 3 in. The screen is 48 × 84 in., set at 25° slope, and vibrated 860 times per min. by a 10-hp. motor. Cloths are 1 1/4- and 3/16-in. The upper half of the upper deck is guarded by 2-in. sq-m. screen of 3/8-in. wire to avoid overloading the lower deck.

St. Joe screen has a ratchet-impact type vibrator. Screens are driven in pairs, by V-belt and countershaft, from a 3-hp. motor. Table 32 gives data on St. Joe screens in S. E. Missouri.

Lead-belt screen. The vibrator (Fig. 33) is mounted on two hickory rods *19* carried on the screen frame. Shaft *5*, driven by pulley *7*, carries, keyed to it, the heavy disk *4*, which is unbalanced by coring out holes *9* and filling them with wooden plugs. The vibration caused by rapid rotation (1,200 to 1,250 r.p.m.) of the disk is transmitted through ball bearings *6* to the hammer *1*, of which *2* is an integral part. A bronze bushing *12* and hardened-steel roller *14* are mounted on *2* and are surrounded loosely by the oblong ring *15*, which is shrunk within the upper portion of transmitter *16*, the lower end of which is attached to a cross bar on the screen cloth. The roller *14* strikes the inside of ring *15* only at the top and bottom of its circular path, thereby transforming the circular motion of the hammer into up-and-down motion of the transmitter. The spring mechanism *22*, *23*, *24*, and *25* is used on large screens to take some of the load off the transmitter..

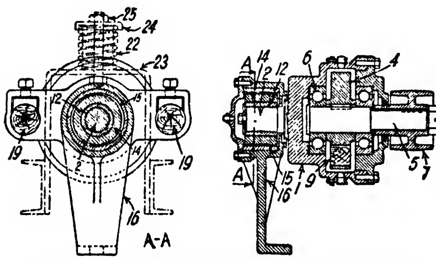

FIG. 33. Vibrating mechanism of Lead-belt screen.

At ST. JOSEPH LEAD CO. a 42×45-in. machine with 1.7-mm. wire cloth formerly screened 25 tons per hr. wet, using spray water. The feed contained 45% < 2-mm. material and the oversize 13.5% < 2-mm. At the same plant a screen 33 in. wide × 7 ft. long with 9-mm. openings handled 33 tons per hr. of dry feed at 70% efficiency.

Multirap screen combines a substantially circular throw with a simultaneous impact. The throw mechanism, situated across the top of the screen box near its feed end, is an unbalanced shaft practically identical with that on the Plat-O screen (Fig. 46). Weight of the box is carried by four trunnions, one at each corner, each passing through a thick pad of crepe rubber encased in a circular housing mounted on the foundation frame. The screen cloth is permanently fastened to the rims of removable panels; 2, 3, or 4 panels, each 2 1/2 ft. long, comprising the screen surface. At quarter-widths, the cloth of each panel is reinforced underneath by a longitudinal channel-form bar *a*, Fig. 34, and above by a corresponding strap, bolted through. The ends of the longitudinal bars under the cloth are semirigidly connected to the end members of the panel, and are also connected crosswise by light angles, forming a rigid but movable lattice beneath the cloth. Impact is applied at the center of each panel by the device shown in Fig. 34. The hammer *b*, with its two striking faces *c*, is mounted at the middle of the flat spring *d*, and constrained by the four spiral springs *e*; hammer and springs are designed to develop an amplitude, at this point, of about 3/8 in. from the 1/64-in. (@ 3,500 r.p.m.) throw of the screen box. Length of the striking pin *f* is adjusted, by the nuts *g*, until its head is struck with the desired intensity of impact on either the up or the down stroke, usually not on both strokes; if wear on the faces *c* should seriously reduce the force of impact, the shims *h* may be removed. The entire impact mechanism is enclosed in a narrow dustproof compartment crosswise of the panel. The manufacturer claims a duty in 30-m. dry screening of 0.8 ton per sq. ft. per hr. as compared with 0.14 ton on a mechanically adequate simple unbalanced-shaft screen of his own manufacture.

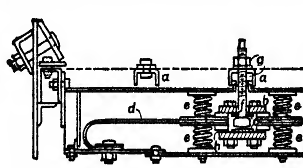

FIG. 34. Impact mechanism of Multirap screen.

Williams Kam-Tap screen is hinged at the lower corners and suspended at the upper end by a vertical rod terminating in a yoke. A roller closing the yoke hangs upon a cam with 4 to 8 arms; rotation thereof produces vertical oscillation of the screen frame, gravity being the restoring force.

Magnetically Vibrated Screens

All screens of this class are activated by a.-c. electromagnets; in one type, direct current is imposed upon alternating, or applied independently, to increase the mechanical effort. The chief points of difference among the several types relate to: (*a*) presence or absence of impact; (*b*) use or avoidance of springs as a reservoir of energy; (*c*) manner of applying the magnetically induced vibration to the screen; (*d*) direction of the vibration with respect to screen surface. Owing to the high frequencies attainable, with necessarily small amplitude of vibration, the principal field for the magnetic screens is fine sizing, wet or dry. Compared with mechanical vibrators, their great advantage lies in the absence of rotating elements requiring lubrication and protection. Nearly all types, however, require special generating or modifying equipment to convert the customary available power supply into current appropriate for the screen. The field of most efficient work is for separation at 1/2-in. and smaller with feeds not coarser than 1-in. limiting. Suitable feed size decreases with decrease in amplitude.

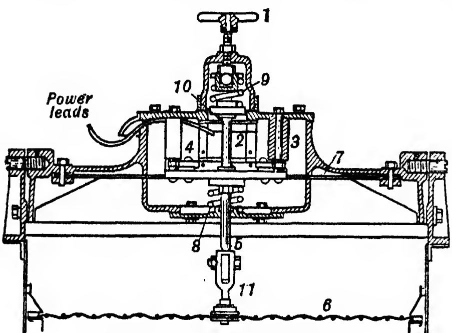

Fig. 35. Hum-mer vibrator.

Impact Type

Hum-mer screen. The cloth is stretched crosswise and attached to the side walls of a stationary box. Vibration is applied at the center of the screen, and normal thereto, and is transmitted lengthwise by straps bolted through the cloth above and below, along its centerline; in some of the larger sizes, vibration is applied at the two quarter-points on the centerline. The vibrator, made in several sizes depending on screen area and load, is mounted on a bridge crosswise of the box. Fig. 35 illustrates its principle. The electromagnet *2* is firmly bolted to the cover of the casing. The armature *4* is maintained in central position by the ribbon spring *7* and is restrained in both vertical directions by the helical compression springs *8* and *9*, the latter acting through the post *10;* amplitude of vibration is governed by pressure applied through the hand wheel *1*, and is adjusted to

allow the ends of the armature to strike the blocks *3* with such impact as may be required for effective screening. Vibrations and impacts are transmitted to the screen *6* through the connecting rod *5*, adjustable in length, and the yoke *11*.

Standard screen widths are 3 and 4 ft., but with most types it is possible to combine two units, side by side, for feeding from a common source. Usual inclination, 33°. Driving force may be drawn from a belt-driven generator or a motor-generator set (usually 15 cycle), or from thermionic, phanotron, or thyratron rectifiers. Frequencies available by the above means are 900, 1,800, and 3,600 v.p.m. Amplitudes are from 1/32 to 1/8 in. in the vibrator, amplified somewhat by the screen. The manufacturer does not recommend use of apertures coarser than 1/2 in.

Performance data are given in Tables 33, 34, 35.

At Copper Cliff (*A TP 901*) each 6 1/2×12 1/2-ft. Marcy rod mill, crushing 625 to 800 tons (average 700) new feed per day to about 65-m., is in closed circuit with a Dorr FX, 12×28 1/2-ft. classifier, handling a circulating load of 250%. As an experiment, the classifier in one circuit was replaced by three 4×5-ft. Hum-mer screens with Ton-Cap No. 2475 stainless steel cloth (10×41-m.;

opening 0.0093 in. wide; wires 0.018 and 0.025-in.). Maximum capacity of each screen was 210 tons new feed per day, returning 30% to the mill. Feed to screen contained 70% solids; undersize (plus spray water), 40 to 42% solids. Table 35 gives sizing tests. No blinding and no appreciable wear in 15 days, whereas a plain steel screen under same condition was blinded with rust in 40 hr. A stainless-steel screen with nearly square (41×50-m.) openings was quickly blinded. Screen products showed no segregation of values. In this mill, selective grinding of heavy sulfides is desirable, hence the alteration was not adopted. The test demonstrated the possibility of avoiding selective overgrind of heavy mineral by closing circuit with a screen. (See also Sec. 5, Art. 12.)

Tyler "400" screen. Four vibrators similar to the Hum-mer, one at each corner of the screen, activate the screen frame and thus vibrate the cloth normal to its surface. Usual speed, 3,600 v.p.m.; usual inclination, 30 to 38°. For performance of two of these screens at New Jersey Zinc, see Table 34.

Non-impact Type

Jeffrey-Traylor "FB" screens. The electromagnetic activating device is shown diagrammatically in Fig. 36. The stator, with its two coils, is rigidly suspended from the

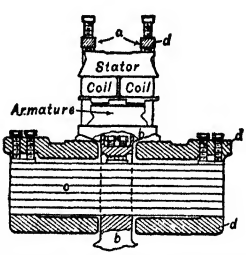

Fig. 36. Jeffrey-Traylor magnetic vibrator.

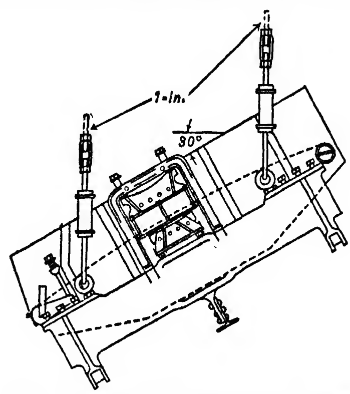

Fig. 37. Assembly of Jeffrey-Traylor screen.

two yokes a. The armature is fastened to the yoke b, which encircles and clamps the composite leaf spring c and is attached at its other end to the screen frame. The steel spring bars c are of the length, section, and number needed for damping and restoration in view of the gravity load. The casting surrounding and supporting the vibrator is made heavy enough to serve as an inertia anchor against the screen and load. There is no impact. Amplitude is governed entirely by rheostat control of the electrical input, but is very small in any case; frequency is claimed to be twice that of the power supply, unless modified. If additional force is needed, direct current may be imposed upon the alternating, or may be directed through a separate magnet circuit; in either case, amplitude is gained at expense of frequency. Two vibrators are mounted (Fig. 37), one at each side, on the inclined side members of the stationary outside frame, and transmit their vibration to the screen box. The entire mechanism is suspended, and its inclination (± 30°) adjusted, by hanging rods and helical springs (Fig. 37). Screen cloth is stretched endwise and is supported, on a curved profile, by rubber-covered cross bars. Applicability is limited to fine screening with light on-screen loads on account of low turnover.

Performances are presented in Table 36.

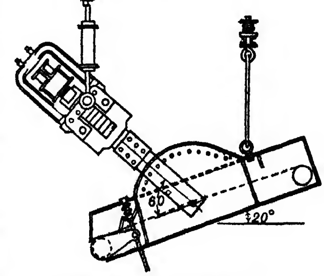

Fig. 38. Conveyanscreen.

Conveyanscreen (Fig. 38). The heavy inertia-anchored vibrating device is hung above and across the screen box in such position that the direction of vibration is oblique to the long dimension of the screening surface, at an angle fixed at about 60° or adjustable. Slope of the screen surface is adjusted

Utah screen (Fig. 39) uses a small-amplitude a-c. vibrator with heavily constrained armature of the general type shown in Fig. 36, but differing in that a split current produced by a copper-oxide rectifier is so led to two electromagnets *e*, located respectively above and below the armature *f*, that each successive half wave produces an oppositely directed impulse on the armature, thus producing positive reciprocation. The ends of the laminated armature are rigidly fastened by post clamps *b* to the heavy inertia-fixed castings *g*, one each side, which are suspended by spring and cable from clips *h* at the corners. Screen box *a* is mounted on cross beams *i* so as to interpose additional resilience between armature and box and thus amplify the vibration. Slope is 25 to 40°; variable in the suspension. Limited in utility to fine feeds.

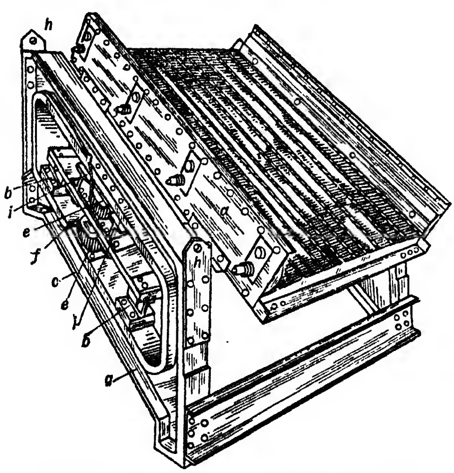

FIG. 39. Utah screen (*Allis-Chalmers Mfg. Co.*).

Performance. Each of the 12 fine-crushing units at MAGNA has six 4×5-ft. Utah screens in closed circuit with rolls (Fig. 16, Sec. 2), treating ore <1-in. feed. In a test period each screen handled 1,840 tons (including 501 tons new feed) per 24 hr. Table 37 gives sizing tests. Average moisture, 5.03%; increase causes blinding. Screen cloth, 4×10-m. 0.028- and 0.041-in. steel wire, lasted 7 days; it required 2 men 6 min. to replace. Slope, 40°; speed, 3,620 v.p.m.; installed power, 0.6 kw. per screen. Screen was fed direct from the head of an elevator.

Sherwen screen (*148 CG 118*) (Fraser & Chalmers) utilizes a half-cycle current from Westinghouse metal rectifier to energize an electromagnet, the armature of which is attached to a screen frame. The back stroke is produced by springs. All moving parts are spring-supported, to increase amplitude. Vibrator is attached near the feed end of the screen.

Locker's Supreme screen (*140 CG 1107*) employs a full-cycle current through a magnet on each side to vibrate the screen frame with corresponding frequency. The screen has two decks; screen is stretched longitudinally; slope increases toward the discharge end.

8. CLOSED-PATH VIBRATORS

These machines were developed in response to a demand for vibrating screens cheaper than the magnetic, and less noisy and better mechanically than the impact types. As it

turned out, the early eccentric-driven machines were also better adapted to handling coarse feeds and heavy on-screen loads than their predecessors. At present mechanical advances in the unbalanced-pulley type are gradually increasing its applicability to heavy loads. It is probably more widely used for fine screening than the eccentric-drive type on account of better control of vibration intensity. Eccentric- or positive-drive machines are used generally for screening at $^1/_2$-in. and up and are sometimes used down to $^1/_4$- or $^3/_{16}$-in. separations. The unbalanced type should not, in general, be used for feeds coarser than 1 $^1/_4$- to 1 $^1/_2$-in. limiting nor for separations coarser than $^1/_2$-in.

Eccentric-drive Machines

In screens of this type a balanced eccentric shaft is mounted on the main frame and the follower bearings are rigidly attached to the screen box. The screen box is either wholly supported by the shaft, or partly by the shaft and partly by some flexible means such as rods, cables, springs, rubber, or combinations thereof, or wholly by the latter means. The screening surfaces are variously supported in the box. Each of the items, *viz.*, the place and type of mounting of the follower bearings; the place and type of auxiliary support of the box, including the relative weights of main frame and box; the weight and distribution of the live load; the mounting of the screen surface; and, to a minor extent, the eccentric and its mounting, affects the character of the vibration. The resultant of all of these effects at any given point on the screening surface determines the motion and screening action *at that point;* the resultants throughout the structure, taken with the nature of the latter, determine structural competence, *i.e.*, *life.*

Much foolishness has been printed and spoken about closed vibratory paths in screening. The fact is that relative to a reference point independent of the screen structure—and this means, among other things, the particles on the screening surfaces—the vibratory paths of every part of the structure are different, no two successive paths of the same point are alike, and it is probable that no one such path is free of inflection. In other words, the paths are not circles or ellipses, even under the most favorable circumstances, but rather irregular erratically wavy curves of generally circular or roughly elliptic outline, changing more or less slightly as one part of an unloaded screen gets into or out of synchronism with another, and changing considerably, continually, and erratically with the live load. The important considerations are whether the motion is at all times sufficient to stratify the bed, keep it moving fluidly, and combat blinding without shaking screen and supports to pieces.

Types of eccentric-drive machines differ in the details of the vibrator, whether the screen box has auxiliary support, and in the mechanical nature of such support. Since variations in vibrator are minor, the screens may be grouped as WITHOUT AUXILIARY SUPPORT; SPRING-SUPPORTED; RUBBER-SUPPORTED.

Eccentric-type vibrator. Fig. 40 shows a form of eccentric vibrator, the elements of which are present in all so-called circular throw screens. Beams *a* are parts of the main frame; they carry the self-aligning ball bearings *b* for the eccentric shaft *c*. Eccentric shoulders *d* run in self-aligning roller bearings *e* mounted on the side plates *f* of the screen box. A V-belt drive sheave *g*, a flywheel *h*, and an adjustable balance wheel *i* are mounted on *c*. Housings *k* protect the flywheel and balance wheel; tube *l* acts both to protect shaft *c* and as a necessary structural stiffener. Speeds are usually about 1,000 v.p.m. and amplitudes $^1/_8$ to $^3/_8$ in., increasing to $^1/_2$ in. for material that tends to blind badly, *e.g.*, splintery material like coke.

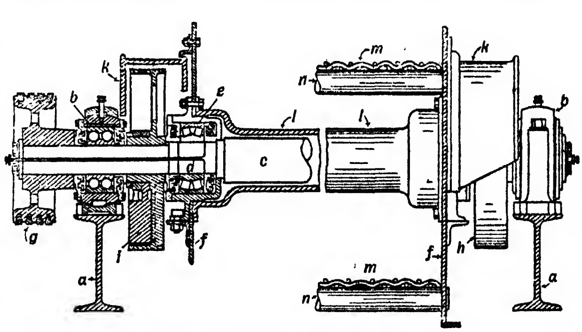

FIG. 40. Typical eccentric-type vibrator.

Without Auxiliary Support

Vibrator screen (Stephens-Adamson) is typical of the simplest form of eccentric-driven machine. Screen box *f* (Figs. 40, 41) carries the screen drawn taut longitudinally between transverse stretchers *y* at each end. It is supported against whip by rubber-covered bow

rods *n*, which run across the box in a plane somewhat above that of the corresponding stretchers. The weight of the box and rock load are carried entirely on the housing of the eccentric followers *e*, which are so placed that shaft *c* runs approximately through the *center of gravity* of the loaded screen. Rocking of the box around shaft *c* is prevented by the pantograph stabilizer *v*, which is fixed at its lower ends to the flywheel guard *k* and across the upper bar to *f* by bolts *z*. Slots for bolts *z* permit variation of tilt, and anchorage of *k* to beam *x* through bolts *t* and bearing *s* maintains the inclination (22° ±).

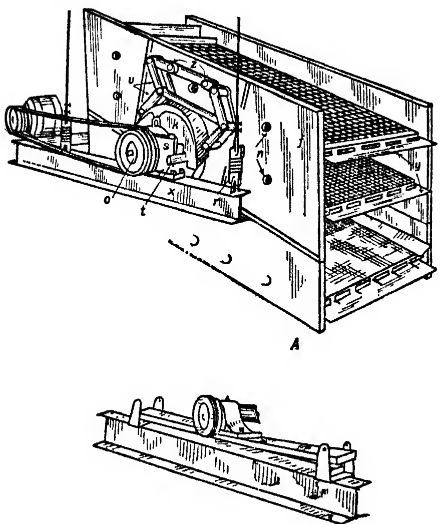

FIG. 41. Vibrator screen (*Stephens-Adamson*).

The vibrator is that shown in Fig. 40. It and the attached screen box are supported on beams *x*, one each side, these in turn being supported on the cable-spring combinations *r*. An alternative support is shown in Fig. 41, item *B*, in which the eccentric-shaft main bearings are carried on the cradle spring on the supporting beams.

The vibratory path of that part of the box near the shaft is generally circular so far as an indicator card backed against the screen assembly is concerned, but against a card carried on an independent support it is more or less irregularly elliptical with the major axis tilted at an angle from the vertical dependent upon the weight of the assembly and live load, the length of the supporting cables, and/or the resistance of the springs. Near the ends of the screen box the path is noncircular even with respect to a point on the support, due both to flexure of the box and to rock of the pantograph; the absolute path here is a resultant of this primary distortion and that due to movement of the whole assembly. Disregarding irregularities, the absolute path of an element of the screening surface is probably bluntly elliptical near the transverse centerline of the surface and pronouncedly elliptical toward the ends, with the upward inclination of the major axis more nearly counterflow when the direction of rotation is counterflow at the top.

Spring-supported Box

Niagara screen. A vibrating mechanism similar to Fig. 40 is mounted *at the center of gravity* of the screen box. Most of the weight of the box is supported, at the four corners, by brackets engaging helical springs which rest on the side members of the outside frame. The latter is usually suspended by rods or cables without springs, attached at the four corners. Screen cloth is stretched sideways, with an upward antiwhip bulge over longitudinal supporting bars.

The effects of taking up more or less of the box weight on springs near the end is to decrease the difference in amplitude of vibration between ends and mid-section of the screen, and probably to iron out some of the waviness of the vibration curve at the ends. The load on the eccentrics is also decreased, which is an advantage mechanically.

Performances are given in Table 38. Table 38*a* shows quality of products at BUFFALO ANKERITE mill, where the screen was in closed circuit with cone crusher and rolls.

Gyrex screen (Fig. 42) has a vibrating mechanism *c*, similar to Fig. 40, located *at the center of gravity* of the screen box. The screen box is carried by flat springs *a* near

each end of the box, set edgewise, bolted at the middle to cross bars forming part of the box frame. These flat springs project through rectangular openings in the side plates of the box and are rigidly fastened to the ends of two longitudinal leaf springs *b*, set flatwise, one on each side, attached at their middle points to the casings of the drive-shaft bearings. The lateral springs thus accommodate the longitudinal, and the side springs the vertical component of the circular throw. The screen box can be tilted 30° in either direction and is fixed in position by a slotted link bolted to the base. Eccentricities are standardized at 1/2-in. The manufacturer recommends 625 @ 1/2-in. throws per min. for screening at 1/2-in. and coarser, and 1,000 at 1/4-in. s.p.m. for 3/4-in. to 20-m. operation.

a Screen aperture, 0.5-in.

Performance at CLIMAX MOLYBDENUM is shown in Table 39.

Sizing equipment of N. Y. TRAP ROCK CORP., at Clinton Point (*34 #9 RP 65*) includes four tandem pairs of Gyrex screens. First of each pair is a 4×8 1/2-ft. single-deck with 2-in. square opening; second is a 5×10-ft. double-deck with 3-in. square openings on the upper, and 2-in. openings on the lower deck. All screens are of alloy-steel wire. Individual motors are 5 hp. for the single- and 10 hp. for the double-deck; total, 60 hp. for eight screens. Output of 800 tons per hr. is often treated efficiently on three pairs of the screens, which is 7.8 tons per sq. ft. per hr. to the primary screens, or 3.7 tons per sq. ft. per 24 hr. per mm. of aperture.

b V-belt drive.

Allis-Chalmers Style B Centrifugal screen has a vibrating mechanism essentially like that of Fig. 40, situated *across the top* of the screen box at its mid-length. The box is suspended at the four corners by springs and rods depending from the side members. These, in turn, are suspended in inclined position by cables and springs. It is claimed that the motion path is substantially a vertical circle at the point of actuation, and becomes elliptical, with the long axis of the ellipse inclining forward at the upper, and backward at the lower end of a single-deck screen. The effect of such motion would be to accelerate flow over the upper end and retard it near the discharge end. On the lower screens of a multideck box, the distortion is said to be greater, in the same sense, but diminished in intensity.

The machines are designed for heavy duty at coarse sizes, up to 6-in. openings with 1-in. rods; they have handled iron ore containing lumps up to 250 lb. weight. Coverings are clamped at the sides and rest on longitudinal rubber-covered bars; the degree of crosswise upward curvature is adjustable.

Telsmith Pulsator has a vibrating mechanism similar to Fig. 40. Driving shaft lies *across the top* of the screen box, which is supported on helical springs (one at feed end, three at discharge end) on the centerline. Inclination (usually 18 to 20°) can be varied 4° by adjustment of compression in these

springs. Screen cloth is not under tension but is attached to frames, two for each deck, held in place by longitudinal side strips.

Link-Belt PD screen has an eccentric vibrator similar to Fig. 40, but attached to the screen box *underneath*, at mid-length. Part of the weight of the box is carried by two longitudinal multiple-leaf springs *a* (Fig. 43), one on each side; the ends of the upper leaf are coiled into flat helical springs *b* of which the centers are pinned to brackets under the sides of the box. The leaf springs are fulcrumed at the middle on a cross bar *c* forming part of the main frame *f*; tilt is adjustable and is maintained by bolts passing through slots *d* in the side members. Average slope is 25°. Table 40 shows performance of PD screens in the Freda mill, COPPER RANGE CONSOLIDATED.

Huron Heaviduty screen (*11 MMt 409*) has the box supported at its four corners on the ends of longitudinal leaf springs, one on each side, which curve upward. The two lower corners are suspended by links hanging from the leaf springs, while the high corners stand upon links erected on the ends of the springs.

a Double-deck screen, but only one deck used.
b Blinding may be serious with occasional damp ore.
c All dry screening.

Roto-Vibratory screen, *at its upper end*, has a horizontal shaft rotating in fixed end bearings. Near each end, the shaft carries an eccentric, the two being opposed 180°. Each eccentric runs in a ball race enclosed by a hollow shaft fastened to the screen box. The low end of the screen is suspended by yoke and flexible connection, adjustable in length, from an overhead cross beam, or rests on spring or rubber supports. Screen cloth is taut crosswise (*10 #2 Coll. Eng., 62*). The motion is not unlike that of the Mitchell screen (p. 57) except that it is positive so far as the head end is concerned.

Rubber-supported Box

Ty-rock screen, intended particularly for coarse work, differs from the Niagara (which it otherwise resembles) in that each of the main bearings of the driving shaft is supported by a short yoke, both ends of which rest on rubber cushions on the outside members. Weight of the box is distributed also to four similar rubber cushions at the corners.

At SHASTA DAM 1,200 to 1,400 tons of <9-in. gravel hourly was screened in 2 stages, 2 @ 2-deck 5×10-ft. Ty-rock screens in parallel in each stage. The first pair of screens had 6-in. and 3-in. cloth woven of 1-in. and 1/2-in. rod respectively. The second pair had 3/4-in. and 3 1/2-m. cloth, the coarser woven of 1/4-in. rod. The <3-in. product of the first screen comprised the bulk of the original tonnage. It yielded 300 to 350 tons per hr. through the 3 1/2-m. screen. The tonnages per 24 hr. per sq. ft. of nominal screen areas per mm. of aperture were 8.2 and 28.4 for the 3-in. and 3 1/2-m. decks respectively.

At MORENCI each of 4 @ 6×14-ft. screens receives 1250 tons per hr. of <8-in. primary crusher product. Covering is 1 1/4-in. Ty-rod with 3 1/8-in. aperture. Each of eight @ 5×10-ft. screens with 3/4-in. aperture takes 625 tons per hr. of cone-crusher product. Feed rates correspond to 4.6 and 16.3 tons per sq. ft. per 24 hr. per mm. of aperture. At the ALCOA plant in Guiana a 5×12-ft. two-deck screen has 60-lb. rail spaced 6 in. for the upper deck and 2 1/2-in. cloth on the lower deck. It is fed steam-shovel rock at 600 tons per hr. At INTERNATIONAL NICKEL a 6×14-ft. two-deck machine with 3 1/4- and 1 1/2-in. coverings is fed primary-crusher product at 650 tons per hr. with the last 4 ft. of length blanked off. The same screen with 3-in. and 3/4-in. coverings handled 875 tons per hr., using full decks. At GRAND COULEE 1 @ 5×10-ft. two-deck machine, with 4- and 2 1/2-in. screen, was fed 1,375 tons per

hr. of gravel 12 to 16-in. limiting size. The 2 1/2-in. undersize was sent to 5×10-ft. screens with 1 1/4- and 3/16-in. openings at the rate of 545 tons per hr. and made 330 tons per hr. through the bottom deck.

Denver Simplicity screen has the eccentric shaft crossing *near the bottom* of a single-deck box or near the *center of gravity* of double- or triple-deck screens. The box rests on cylindrical rubber cushions at the four corners. Screen cloth is stretched and crowned in both directions.

Krupp Universal screen has the typical positive eccentric mechanism at *center of gravity* of the screen box (*10 # 2 Coll. Eng. 61*). Latter is supported at each end on a round cross bar carried on side members and passing through thick rubber flanges, suitably reinforced by metal flanges fastened to the side plates. Main bearings are also rubber cushioned.

Good Roads vibrating screen (*33 # 3 RP 117*). The box rests at each corner upon two 3-in. rubber balls superimposed in a suitable cage on the side members.

Selectro screen has an adjustable throw, and a wide range of inclination which can be varied 0 to 40° without stopping operation. To each end of the cylindrical driving shaft C (Fig. 44) is keyed a dished plate D, the inner rim of which is eccentric to the shaft. The plate F has a shoulder, both faces of which are eccentric, and supports the roller race H; hence, by turning plate F with respect to D (by inserting a bar at J after loosening nut N) the eccentricity of H can be varied in eight steps between zero and 3/8 in. The throw is transmitted through the rollers to the inner raceway H', and thence to the hollow bar B fitting the flanges A on both sides of the screen box, near its *center of gravity*. The stub-shaft E and its pulley may be fastened to either end of the shaft C, the bearing on the opposite side being closed by a plate. The counterweights M, N rotate in same plane as the rollers. Inclination of the screen box is adjusted and maintained by four arms hinged to a rotatable casing surrounding the shaft; this casing may be clamped in desired position by bolts which cause engagement with the main bearing. Studs at the ends of the arms engage thick live-rubber flanges suitably mounted in the side plates of the box.

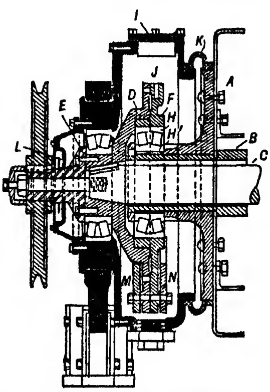

FIG. 44. Throw mechanism of Selectro screen.

Performance. At NEW JERSEY ZINC Selectro screens are used for fine screening. The finest (0.042-in.) takes oversize from a preceding (0.023-in.) Tyler "400" and delivers its oversize to the next coarser Selectro, which repeats the process with the next coarser, as shown in Table 41*a* and the flow-sheet, Sec. 2, Fig. 106. Operating data are in Table 41. The ore is thoroughly dry. At an ILLINOIS coal plant a 4×8-ft. Selectro is fed 100 to 125 tons per hr. of <1 1/4-in. coal. Top deck has 1-in. aperture, second 5/16 × 1-in., third 10-m. With a total screen feed of 103 tons per hr. the bottom deck received 27.5 tons per hr. and passed 18.5 tons per hr. In another run 125 t.p.h. was sent to the screen and 48.8 tons reached the bottom deck, which passed 31.2 tons or 1.2 t.p.h. per sq. ft. of 10-m. screen surface. The spread in screen sizes was too great for efficient operation of all decks; tilt was set to favor the bottom deck, and the oversize of the top deck carried some <1-in. material. At another time, with new-feed tonnage probably within the range above, the oversize of the bottom deck contained 1.7% <14-m.

a All screens: 4×10-ft.; 5-hp. motors, Tex-rope drive, 2 1/2 hp. consumed; Ty-rod cloth; cleaned once per shift; 2 men require 1/2 hr. to replace. For size of feed see Table 41*a*.

Unbalanced-throw Machines

Screens of this class are alike in the fundamental element that they all utilize the gyratory force developed by mounting an unsymmetrical body on an unstable base and then rotating the body at high speed around an axis not passing through its center of gravity. The resultant translatory motion is constrained sufficiently by gravity and resilient ties to produce vibration in roughly closed paths of the same general shapes as those discussed on p. 49, but more erratic, and showing much greater response to changes in live load. Amplitude and the direction of prevailing eccentricity of path depend upon: (*a*) mass,

speed, and eccentricity of the unbalanced member; (*b*) position of the rotator with respect to center of gravity of the loaded box; (*c*) constraint imposed upon the screen box by the manner of its support; (*d*) weight of material on the screen.

The screens of this type differ from each other in the method of producing (and controlling) unbalance in the rotor, in the location of the rotor, and in the manner of supporting the box and constraining its motion. The combinations of these variables are too diverse to permit any logical classification. The most apparent structural difference is in the location of the vibrating mechanism. Speed is usually 1,200 to 1,800 r.p.m. and the corresponding amplitude range $^3/_{16}$ to $^1/_{16}$ in.

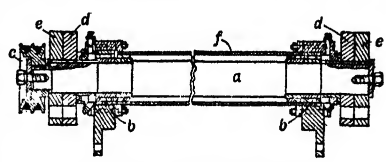

Fig. 45. Unbalanced rotor.

Unbalanced rotor. A simple form is shown in Fig. 45. It consists of the symmetrical shaft *a*, roller bearings *b* attached to the screen box, a drive pulley *c*, and two unbalanced flywheels *d*, *e* near each end. Flywheels *d* are keyed to *a*. Flywheels *e* are adjustably locked to *d*. Both are usually equally weighted so that the degree of unbalance of the rotor as a whole may be varied from zero to a maximum by suitably setting the relative positions of the weights of *d* and *e* before locking. Tube *f* is primarily a stiffener and tie between bearings *b*; secondarily it serves as a dust guard and protects the shaft from wear.

Vibrator at Top of Screen Box

Plat-O screen (Fig. 46) comprises the vibrator *a*, substantially as described above, mounted on top of the sidewalls of the screen frame *b*; eight supporting springs *c*, four each side; a supporting frame consisting of longitudinal members *d* and cross ties, suitably stiffened; and one or more screen decks *e*, drawn taut lengthwise between clipbars *f*, and stretcher assemblies *g* mounted on the back of the box. Cross pipes *h* stiffen the side walls and support the screen against whip; they are rubber-covered to reduce wear. The box is open at the top but usually has a bottom for transport of undersize for front delivery.

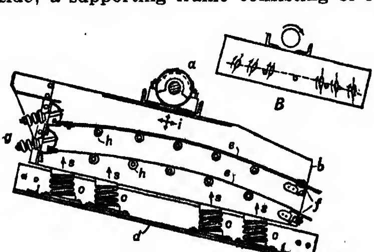

Fig. 46. Plat-O screen.

Direction of rotation is clockwise in the view shown, *i.e.*, WITH-FLOW, or CON-FLOW. The small ellipses shown in item *B* represents the manufacturer's idealisations of vibratory paths at different points along the length of the screening surface. It is apparent that with the lines of action of impulse *i* and support *s* as indicated, the resultant path could be circular only in the miraculous case when the resultant of the dead and live (rock) loads of the box completely balanced at all times the instantaneous resultants of the continuously variable *i*'s and erratically variable *s*'s. But a similarly miraculous constant difference

between the resultants of the two sets of forces is a necessary condition precedent to the elliptical paths indicated. Rough ellipticity of all paths certainly exists. Inconstancy both as to axis ratios and directions is just as certain.

Link-Belt UP screen (Fig. 47) has the box *a* supported on each side by a composite leaf spring *b* of which the upper leaf curves upward 180° at both ends to connection with the upper flange of the box. The vibrating mechanism *c* lies across the top of the box, at mid-length. The body of the rotating shaft is eccentric to its bearings; the amount of unbalance, thus fixed, is made adjustable by addition of a movable unbalanced flywheel on each end of the shaft. Screen covering is stretched transversely. The lower of two decks is independently mounted in a separate frame which can be attached below that of the upper deck.

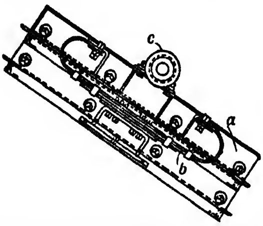

FIG. 47. Link-Belt UP screen.

Performance. At the Maitland mill of the CANYON CORP., a 3×5-ft. screen, with 0.170-in. apertures and inclined 25°, handles 10 tons per hr. of new feed at 1/2-in. limiting size, plus an estimated 15 tons of circulating load (Q). Ore is hard and siliceous and has 2% moisture. Screen of 0.080-in. steel wire lasts 30 days; is replaced by 2 men in 1/2 hr. A tendency of the cloth to slip and tear before being completely worn was corrected by fastenings at top, middle, and bottom on the centerline. Strokes, 1,720 @ 1/8-in. per min.; driven by V-belts from 2-hp. motor.

Aero-Vibe screen consists of a rectangular box *a* hung at each corner by cable from a helical spring: usual inclination, about 20°. The vibrating mechanism is that shown in Fig. 45. Cloth is stretched transversely.

Vibrator Near Center of Gravity

Denver-Dillon screen has flywheels at the ends of a shaft carried on roller bearings at the centers of gravity of the side plates; each flywheel has a weight which can be bolted at the desired distance from the center to vary unbalance. The screen cloth is stretched crosswise. The screen box is suspended, near its corners, by four vertical rods, all of the same length not exceeding 42 in.; the rods are attached to the box by pivoted brackets, and are supported at top on helical compression springs, preferably mounted on an overhead frame. Inclination of the frame, averaging 22 1/2° and adjustable ± 8°, fixes the slope of the screen. Usual speed is 1,000 v.p.m.

Performances are given in Table 42.

Vibrator Underneath Box

Vibrex screen has the box supported by two-armed yokes along the sides; the arms rest in horizontal position on springs which, in turn, rest on foundations or on a suspended frame. Circular casings welded to the side walls of the box are carried in the neckpieces of the parallel yokes. Their centers are on the transverse centerline of the box; thus, with suitable set nuts slotted in the yoke, tilt is adjustable. Gyration is effected by unbalanced weights rotating with adjustable radius, in the above-mentioned casings, on a shaft extending across the bottom of the screen box. Screen is stretched transversely.

Miscellaneous Types and Positions of Vibrator

Mitchell screen. The sides of the screen box are suspended from the ends of the vibrator. The latter (Fig. 48) comprises a cylindrical tube forming both a strong beam and a frame for a motor A, the shaft of which carries a ball cage D at each end, while the ball races E are carried at the ends of the beam. In the form shown the cages and races provide for four balls; in another form there is one 2-in. ball only at each end. The vibrator is mounted in a spherical seat at its center, on a saddle supported on a self-contained structural-steel framework. It is thus free to follow a path generating a double cone with base diameter of about $^1/_{16}$ in. and apexing at the center. The hanging screen box follows, with the path of any portion of the screen modified by the resilience of the side plates of the box and secondary vibration of the side-stretched cloth. Customary speed is 3,600 v.p.m.; motor is $^3/_4$-hp., induction-type. Slope is 35 to 40°.

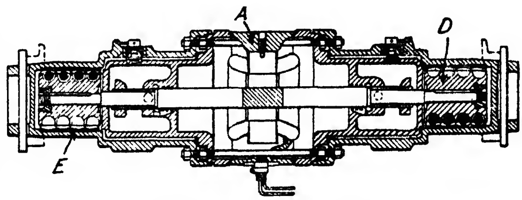

Fig. 48. Mitchell vibrator.

Performance. In the Conda, Idaho, phosphate-rock plant, a 48×60-in. screen with $^1/_2$-in. apertures and inclined at 33° receives 80 tons per hr. total feed; moisture, 5.5%. Oversize contains 10% undersize. Screen of $^3/_{16}$-in. spring-steel wire lasts 130 days and is replaced by 2 men in 45 min. At Miami Copper, in each of the three crushing units, four 66×72-in. Mitchells and one other screen of about the same size, in parallel, receive 550 tons per hr. of new feed from a cone crusher delivering at about 1-in. max. size, plus their own recrushed oversize, or a total load of 150 tons per screen per hr.; moisture, 3 to 3.3% (higher moisture causes excessive blinding). Each screen has two sizes of cloth: $^5/_{16}$-in. on the upper half of the deck, $^3/_8$-in. on the lower. Slope, 33°. Screen, of 0.148-in. wire, has average life of 10.3 days. Power consumed, $^3/_4$ hp., or 0.01 kw-hr. per ton. At Matahambre (*IC 6544*) two Mitchell screens in parallel are in closed circuit with choke-fed rolls set at $^1/_4$ in. and crushing 65 tons per hr. to pass the $^3/_8$×1-in. screen openings; screen oversize, 30 tons per hr. Total screening cost, $^1/_2$¢ per ton. Table 43 gives sizes of feed and products.

Rod-deck screen has a screening surface that is concave upward, the slope flattening gradually from 30° at the feed end to substantially horizontal at the discharge end, of such a length as to give an average slope of about 10°. The screen surface is made of parallel-rod sections (Art. 3). The screen frame rests on a transverse rubber rocker at the head end, so that motion there is substantially linear, at right angles to the rocker, in a plane inclined about 30° from the horizontal in the direction of flow. The lower end of the box is suspended at the corners on short rods depending from helical compression springs. The mechanism, of the unbalanced-throw type, is supported on the box walls underneath the points of suspension. Hence the motion at the lower part of the screen is of the closed-path type, generally elliptical, and probably with the major axis at a steep angle to the horizontal. At intermediate points ellipticity should increase toward the feed end and the major axis gradually fall into substantial parallelism to the screen.

Performance. Table 44 notes performance at two mills, and Table 44*a* gives size analyses.

At the Loreto Central mill, two 4×8-ft. screens, with $^3/_4$-in. openings, treat the product of a gyratory crusher, set at 3 to 4 in., at a combined average rate of 200 met. tons per hr. Either screen can take the whole load when necessary.

Screens with little or no slope must have the mechanism, if this of rotary type, so designed and placed as to produce a sudden stop or, at least, a quick reversal at the forward end of the path of the screen surface; or the path must be con-flow upward in its upper part and the screen surface drop away from under the load at the forward end of the path.

Low-head screen (Fig. 49). The box *a* is usually suspended at its four corners (holes *b*) by cables and springs, but may be supported on spiral springs on a foundation. Screen is normally horizontal. Vibration is produced by a pair of short horizontal shafts *a*, Fig. 50, rotating in opposite directions, and each carrying two counterweights *b*, all four of which are identical. The two shafts (one of which has a driven pulley) are connected by gear wheels *c*, to maintain synchronism. When the four weights are set so that their centers of gravity all lie in the plane of the shafts, as indicated, the components of force in this plane counterbalance, but the components at right angles thereto are additive and produce a strong vibration in a direction normal to the plane of the shafts. The mechanism is mounted inside the housing *c* (Fig. 49) on a bridge spanning the top of the screen box, and in such position that the perpendicular to the plane of the shafts makes an angle of 45° with the screen surface. The resultant of the vibratory impulses at an angle to the pull of gravity and the vertical supports produces a motion path in the frame that is generally elliptical, with the axis inclined toward the discharge end. The screen surface follows this path more or less. Hence the particles thereon receive upward impulses with a component toward

the discharge end when the cloth is on the upstroke, and the cloth drops from under and backward on the down stroke, whence the particles, falling freely, reach the surface again nearer the discharge point than they left it.

Performance data are given in Table 45 and sizing tests of products in Table 45*a*.

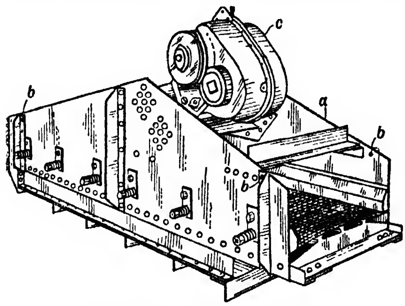

FIG. 49. Low-head screen (*Allis-Chalmers Mfg. Co.*).

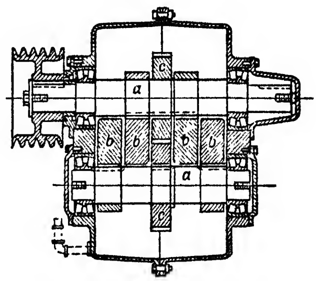

FIG. 50. Mechanism for Low-head screen.

Korb-Pettit screen is similar in principle to the Low-head but the box is supported on six or more flexible flat legs rigidly fastened at both ends and inclined about 45° toward the feed end. Vibration, thus oblique to the screen surface and with upward throw toward the discharge end, is produced by an unbalanced mechanism mounted on a bridge across the top of the box near its mid-length. The mechanism, driven by V-belt, consists of two unbalanced flywheels side by side but on separate and unaligned shafts, gear-connected. The flywheels are so synchronized and their supporting base is so tilted that their combined gyrating effects result in a motion normal to the supporting legs. The screen is said to operate when set level, or even with an upward slope. Usual speed is 800 to 900 r.p.m.

of the distance from feed to discharge end. The combination of eccentric setting of the mechanism and its internal unbalance results, of course, in distortion of the motion curve. The form and direction thereof, as stated by the manufacturers, is shown in item *m*, Fig. 51.

Screen cloth is stretched transversely and appreciably bowed upward to the longitudinal center plane.

Tension on screen surfaces is the usual method of transmitting vibration, however produced, to the load on the screen. One or two manufacturers dispense with it, depending on a grid supported on the walls of the box, to which the screen surface is bolted, for transmission. But adjustable tension provides a means of controlling amplification of primary vibration to a certain extent, and is generally considered desirable. Tension also tends to eliminate valleys in the screen surface—in which material piles into relatively thick layers difficult to screen. It introduces, however, a mechanical problem in that fatigue tends to cause screen breakage along the edges of the tension grips unless special provision is made to prevent flexure stresses at these points. The various forms of tension application shown in Fig. 52 are designed with the aims to prevent flexure, reduce wear, and facilitate quick change.

The essential element in all forms of flexure-preventing mountings is a means to transfer the rocking point or line from the screening surface to the stretcher. This is done most simply by attaching the stretching members in the plane of the stretched surface and providing rocking bearings for them against the walls of the box. A simple form is shown in Fig. 52, item *a*, in which the shank of the stretcher hook is in the plane of the cloth, the hole in the side wall *w* is larger than the shank, the seat of the spring cage against the edges of the hole is conical or spherical, and the hole therein for the shank is large enough to permit considerable play. This construction causes the cage to seat in proper alignment during tightening and transfers rock to the outer plate of the spring cage. A more elaborate form of support employing the same principle is shown in item *b*. This form, which is used in modern Hum-mer screens, is designed to decrease damping of vibration along the edges. Item *c* shows a form of stretcher designed for quick change, in which the rocking point is transferred to the bent edge of the screen surface. The disadvantage of this is that, if any rock occurs, wear occurs simultaneously. This wear may be transferred to a strip of steel pressed onto the edge as in item *d*. If, however, this type of stretcher is modified as in *d* by placing the angle *s* under the screen, the tendency is to transfer the flexure line back to the screen. Another form of bent-edge stretcher is shown in item *e*, in which the stretcher strip has spring bolts as in item *c*; *B* is a rubber-edged skirt board that is swung up out of the way when screen is to be changed. Item *f* shows the use of two stretchers when a heavier backing screen is used with fine screen under heavy loading conditions. Item *g* shows a simple springless form used for longitudinal stretching.

Fig. 52 shows also different methods of gripping the screen surface. Heavy coarse screen may be gripped as in *a* by welding the outer rod to the rods that it crosses. Coarse screen (rods 1/8-in. diam. and up) are usually bent at the gripping edges as in *c*, and usually no further preparation is necessary. With

finer yet relatively coarse cloth, the bent edge is reinforced by bending a selvage strip with the wire, as in *d* (some manufacturers make this selvage strip or its equivalent with steel rubber-covered on the wire side); or welding on a bent strip, as in *e;* or welding or bolting on an angle or strap as in *g* and *b* respectively. With fine cloth, straps or an angle and a strap are placed one each side of the cloth, best with rubber between them and the cloth, and bolted through.

Amount of tension applied differs with the weight of the cloth, and the camber of the whip-preventing frame that underlies the cloth. One manufacturer uses springs in the tension bolts with a sufficient number of bolts to give a maximum of 5,000 lb. per linear ft. When the tension bolts are not spring-mounted, care must be exercised not to overpull light cloth. Best pull must be learned by experience in operation. Cloth with rectangular openings should be placed with the long dimension of the openings

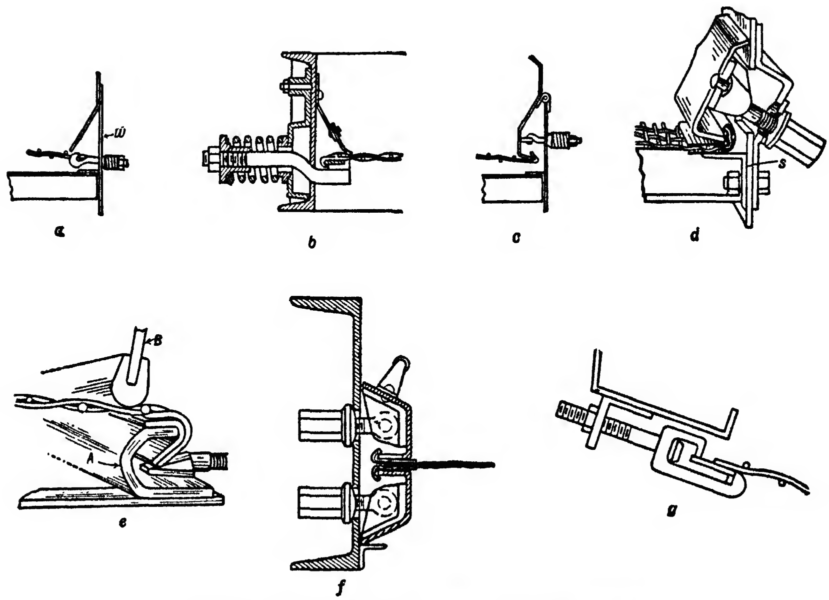

Fig. 52. Forms of tension grips for vibrating screens.

in the line of pull in order to put the tensile strain on the greater number of wires; these wires are also the harder. Grips should be parallel to insure uniform tension. Plentiful use of rubber at all contact points is advisable.

Wear *is greatest, of course, at the feed end of the screen. Panels should, therefore, be so made* as to be reversible end for end.

Effect of whip is to increase blinding, since the cloth is stopped suddenly against the whip frame at the end of the down stroke.

Decks. Multideck screens (2 to 4 decks) are used to save headroom, but this is invariably done at a sacrifice of efficiency, since intensity, slope, and feed rate are critically related to aperture and limiting size of feed to a deck. Intensity is substantially the same on all decks. Best feed rate to two or more decks will rarely, if ever, correlate with the desired screen sizes and the size distribution in the feed to the top deck. The decks may be set at different slope, but this is merely a palliative. The fine decks usually limit the capacity, blind most, require the most screen changes, and are most difficult to watch or to get at for patching or change. Most manufacturers recommend against the use of more than two decks, and this is the limit in ore-dressing plants.

Slope. See under "Operation," p. 62.

Support. Screens in which the screening surface only is vibrated are usually supported directly on the building framework. The vibrating-frame types must be insulated in some way from the building frame. This is done either by supporting the vibrating part on springs or on rubber or by hanging it on flexible supports. Either method may be used in any particular case, but unless special structural demands are prevailing it is usual to suspend the smaller screens and support the larger. Some manufacturers recommend rubber support rather than springs on account of danger of spring breakage. Cables are usually used for hanging because they respond better to the lunging that occurs when screens are started and stopped. A compression-spring cage is usually fitted to one end or

the other of cable suspensions. Large eyes should be used at both ends of the cables. One manufacturer pictures different forms of suspension as in Fig. 53.

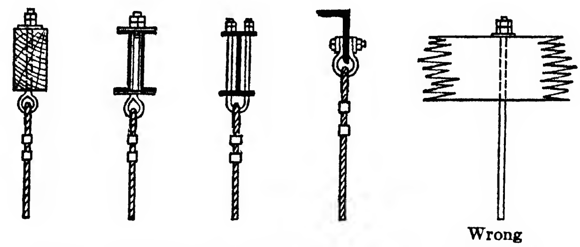

FIG. 53. Methods of hanging vibrating screens (*after Robins*).

Feed and discharge chutes should be given 3 to 6 in. clearance to allow for operating changes in slope and for lunging of the screen at start and stop. Feed box should distribute the material across the screen, should feed on with as little drop and velocity as possible, and preferably in a direction opposite the slope. A common arrangement is shown in Fig. 54. Length of box should be width of screen less 12 in. and box should be centered. Dimension A should be 12 in. for limiting sizes up to 3 in., 18 in. for 3 to 6 in. limiting sizes, and 24 in. for >6-in. limiting. The back (low side) should be high enough so that material at repose will reach the ends of the box. The front should be high enough to prevent splash or spill from the feeder (elevator or conveyor). Dimension B should be adjustable between two and three times the limiting-feed size. Dimensions C and D should be two to three times limiting-feed size. The angle lengthwise of the bottom is a stiffener. A replaceable wear strip should be provided along the discharge edge.

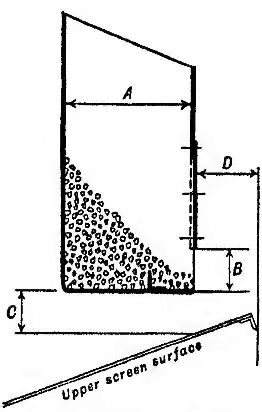

FIG. 54. Gravity distributor for screen feed.

Manufacturers. Allis-Chalmers Mfg. Co., Cort & Sons, Deister Machine Co., Denver Equipment Co., Fraser & Chalmers, Gifford-Wood Co., Jeffrey-Traylor Co., Link-Belt Co., Nordberg Mfg. Co., Overstrom & Sons, Productive Equipment Corp., Robins Conveyor Belt Co., Smith Eng. Wks., Stephens-Adamson Mfg. Co., W. S. Tyler Co., Williams Patent Pulverizer and Crusher Co.

9. OPERATION OF VIBRATING SCREENS

Selection of the most suitable operating conditions usually involves a number of compromises, according to the end sought. The mechanical variables available are slope, intensity of vibration, and, with some screens, direction of impulse. Type of screening surface and aperture are made operating variables in many plants. Variable results are tonnage, efficiency, and life of covering.

Intensity of vibration must be sufficient, in order to aid flow of material over an inclined screen, to at least tilt particles over the obstructions formed by the uneven contour of the screen surface. If the inclination is too slight for the particle to roll when tilted, the vibratory impulses must throw it clear of the surface, and their direction and speed must so correlate that the particle, when it again falls onto the surface, is nearer the discharge end than when it left. Additionally the intensity must be sufficient to lift out particles caught in meshes but unable to pass. It is apparent, then, that intensity must be greater the larger the particle, the heavier the load, the lower the slope, and the greater the tendency to blinding. Intensities recommended for eccentric-drive machines are given in Table 46.

Table 46. Intensities recommended for eccentric-drive screens (*After A. D. Sinden*)

Apertures, in.	Speed, r.p.m.	Amplitude, in.	Intensity
1/16 –1/8	1,200	0.12	144
1/8 –5/16	1,200	0.15	180
5/16 –3/4	1,200	0.18	220
3/4 –1 1/2	1,000	0.25	250
1 1/2–2	1,000	0.27	270
2 –3	900	0.35	315
3 –4	900	0.40	360

Screen movement has the further effect, the more important the heavier the load, of agitating the bed and causing stratification therein according to size, large particles at the top. With on-screen loads one particle deep, which is the ideal condition for presentation, maximum efficiency will be obtained when the intensity is such that a particle of the same size as the effective screen opening (or, on an inclined screen, the horizontal projection of the opening) hits each opening as it progresses along the screen surface. This desideratum must be, of course, modified by the necessity to move the larger oversize.

Over-intensity interferes with stratification, tends to jump near-mesh particles out of apertures before they have had a chance to adjust themselves through, increases length of particle jumps with the result that the effective length of screen is decreased, and increases repair bills for both screen covering and mechanism. Under-intensity decreases capacity and increases blinding. Less intensity is necessary for a given travel with con-flow rotation on closed-path machines.

Intensity is controllable through speed and amplitude. The former is not a variable with magnetic vibrators; it is by pulley changes, with mechanical types and is the control recommended by some operators. In most cases, however, amplitude is changed, because of greater simplicity and the shorter steps readily available. In general, high speed and a stroke as short as will prevent blinding gives highest efficiency for the finer screening; in coarse screening, satisfactory efficiency is usually obtainable at any stroke that will move the bed. When high tonnage is the desideratum, amplitude must be increased in order to agitate the thick on-screen load sufficiently to stratify and flow it rapidly.

Slope, once the point of initial flow of material is passed, acts jointly with intensity to determine rate of movement, and the resultant velocity taken with the feed rate determines thickness of bed. Slopes necessary for flow, all other things being equal, vary with the material treated. A Niagara screen required only 11° slope for a 1 $^1/_4$-in. screen fed with gravel, but 18° on a $^1/_4$-in. screen taking undersize from the first. The same type of screen handling wood chips required 24 to 30°. Crushed rock always requires higher slopes than gravel. Slope must be steeper for counterflow than for con-flow rotation, and for low- than for high-intensity vibration. In general, the flatter the slope, the thicker the bed, the greater the load, and the more blinding, screen wear, and shock on the mechanism. Conversely, the higher the slope, where gravity is an important force in flow, the more missed apertures and the greater the length required for a given efficiency.

Slopes above about 23° begin to reduce the aperture and, consequently, the percentage of opening of square-mesh screens markedly. The effect on rectangular mesh, even when set transversely, is much less marked.

Horizontal screens should be used for normal screening service only when the headroom thus saved is necessary. N. Weil (*PC*) reports that a pitch as small as 2 to 5° increases capacity materially and correspondingly decreases maintenance. They are useful in dewatering or washing and scrubbing.

Direction of vibration is not an operating variable with linear-path screens, but with closed-path machines it may be made so by use of a reversing motor. Where high capacity is the desideratum con-flow rotation should be used; for high efficiency, counterflow. Con-flow operation will pass a given tonnage of oversize with about 8° less slope than counterflow.

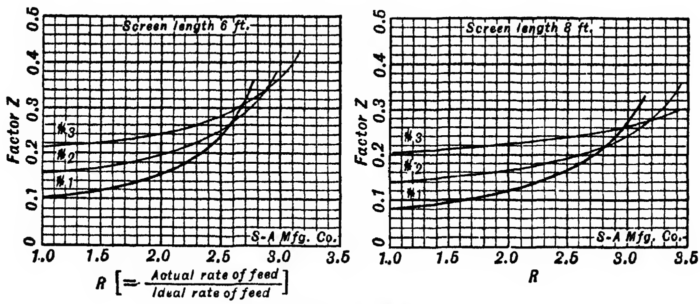
Character of covering. It is usual practice at mills where moisture content of screen feed varies through wide limits to change to screens with larger aperture when, *e.g.*, the rainy or winter season comes along, and *vice versa.* Screen changes require but a few minutes with vibrating screens and much can be done cheaply in ore-dressing plants in the way of control of capacity and efficiency by maintaining a set of screens of different types of surface and different shape and size of aperture to meet varying conditions of feed. Such practice but borrows a leaf from the book of the industrial screening plants, where constancy of covering on a screen is the exception rather than the rule.

It is worth noting that flat slopes, heavy screen loads, and high intensities are hard on screen coverings and that coverings are usually the largest item of expense in vibrating-screen operation.

Capacity. For general discussion see Art. 2.

Overflow method of estimating capacity of eccentric-drive machines is proposed by A. D. Sinden (*PC*). Basic feed rate F_1 is defined as tons per hr. per ft. of screen width that will screen with maximum efficiency at 18° slope with the vibration intensity given in Table 46. The value for F_1 is given by the equation $F_1 = 10QW/C$ where Q is aperture of the square-mesh separating screen in in., W is weight of material in lb. per cu. ft. of struck volume, and C is the percentage of critical size (see Art. 2; here taken as the range 0.75 Q to 1.5 Q). Actual feed rate $F = F_1R$, where R is a factor dependent upon the effi-

ciency factor Z (Art. 2) and the intensity of vibration I. Values of R corresponding to different values of Z and I for 6- and 8-ft. lengths of screen surface are given in Fig. 55. Width of screen is $M = T/F$, where T is hourly tonnage of total feed.



No. 1. Normal vibration intensity.
No. 2. Vibration intensity 50% above normal.
No. 3. Vibration intensity 100% above normal.

FIG. 55. Factors for Sinden screen-capacity formula.

Example. Wanted the size of screen required to separate 250 tons per hr. of bank-run gravel (W = 100 lb. per cu. ft.; size distribution as in Fig. 56.) on a 1-in. square opening, yielding an oversize product containing not more than 10% undersize.

From Fig. 56 there is 20% of critical size (C) in the feed. Hence $F_1 = 10 \times 1 \times 100/20 = 50$ tons per hr. From the specification, $Z = 0.10\ (33.3)/20 = 0.17$. The corresponding value of $R = 2.1$ may be read from the curve #1, Fig. 55, for a 6-ft. screen. This length is chosen because the gravel is free-screening and the efficiency requirement relatively low. For the same reasons, standard intensity will serve. Hence $F = 50(2.1) = 105$ tons per hr. and $M = 250/105 = 2.4$ ft., or a 3 × 6-ft. screen would be required.

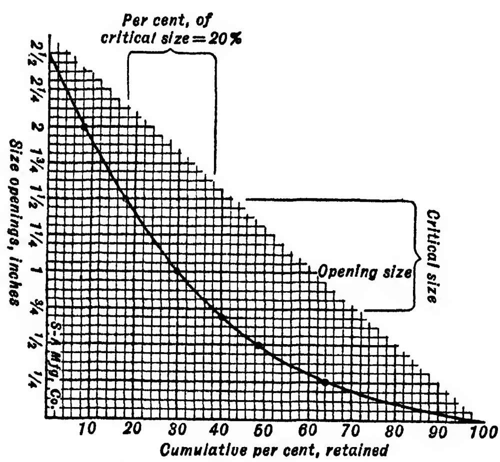


FIG. 56. Screen analysis for capacity formulas.

Through-flow method for eccentric-driven machines is used by Smith Engineering Works (*their Bul 266 K*). The basic through-flow T_F in tons per hr. per sq. ft. of screen cloth area with square apertures of a given size is shown in Table 47 for stated conditions of efficiency (95%) and percentage oversize (25%) in feed. Actual through-flow (same units) is given by the equation $T_A = T_F VEHwD$, where V is a factor (Table 48) corresponding to the amount of oversize of the separating screen present in the feed, E (Table 48) corresponds to the percentage efficiency (by recovery formula, Art. 2) specified, H (Table 48) is the HALF-SIZE FACTOR, corresponding to the percentage of material in the feed that would pass through a screen of half the aperture of the separating screen; w (Table 47) is a wetness factor which takes into account the advantage of wet screening; and D is a factor taking into account the lower efficiencies of added decks, having the values 0.9 for the second deck and 0.75 for the third. (A value of 0.8 is recommended by Allis-Chalmers.) Tonnage of undersize T_U in the hourly feed T is $T(1 - v)$, where v = decimal fraction of oversize. Area of screen surface required $A = T_U/T_A$.

Dimensions of the screen to be chosen to give the required area depends upon the shape characteristics of the particles, efficiency requirements, mineralogical nature of the feed, the form of the distribution curve, and a number of further imponderables embraced collectively under the name "experience." In a way, this means that certain of the elements of the factor tables are weighted twice. Perhaps the safest approach is to bear in

[a] Oversize in feed; specified efficiency (recovery-formula method, Art. 2); or percentage on whole feed less than half-size of the separating aperture.

mind that capacity is a matter of width rather than length; that efficiency is more a matter of length; that experience has led to a general minimum ratio of length/width = 2 for reasonably close sizing of free-screening material; that good screening of free-screening material requires at least 6 ft. in length unless some especially favorable factor is present; and that additional length to overcome a particularly unfavorable situation should be added on rather than included in the area estimate. For the effects of moisture in the difficult range (4% to enough to render the pulp reasonably mobile) see Art. 2.

Example. Take the conditions of the preceding example (p. 64). T_P from Table 47 is 2.56; V from Table 48 is 0.98; E, for an efficiency of 95%, is 0.98; H is 1.20; w for dry screening is 1.0; and D is 1.0, since only one separation is required. $T_A = 2.56 \times 0.98 \times 0.98 \times 1.20 \times 1.0 \times 1.0 = 2.94$. $A = 250(1 - 0.3)/2.94 = 59$ sq. ft. Eccentric-driven vibrating screens are available in widths up to 6 ft. Since 6-ft. width would give a length less than twice the width and 5 ft. would give one more than twice, choose 5-ft. width. Lengths over 6 ft. usually go in 2-ft. steps, hence a 5×12-ft. screen would be required to satisfy requirements. A 6×10-ft. screen would serve, since the material is easy screening. A 4×10-ft. screen would probably be sufficient if water were used.

Total-feed method is used by Link-Belt Co. (*PC*) for both eccentric-drive and unbalanced-pulley type vibrators. Basic rates in terms of total feed T_T of a given struck-volume density, dryness, and percentage undersize are given in Table 49. Values of factors V, H, E (defined as in the preceding case), and a moisture factor m are given in Table 50.

Table 49. Basic capacity factors for mechanically vibrated screens (*After Link-Belt Co.*)

a Oversize in feed; specified efficiency (recovery-formula method, Art. 2); percentage on whole feed less than half-size of the separating aperture; percentage of moisture.

b The usual remedy for the drop in capacity here indicated is to increase screen aperture and/or use screen of rectangular aperture with a ratio of length/width = >10.

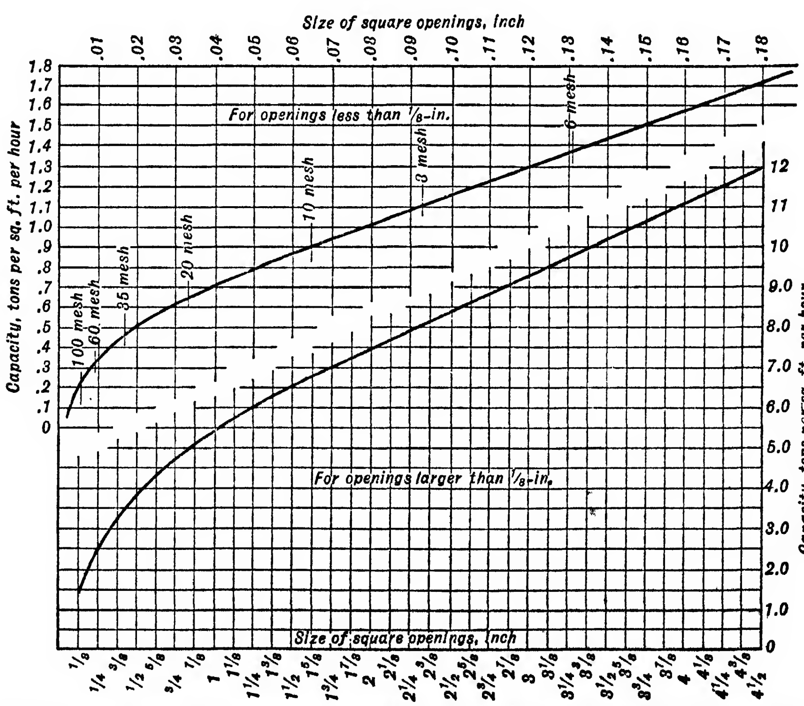

FIG. 57. Basic capacity of vibrating screens. (Feed: dry, crushed, 100 lb. per cu. ft. of struck volume, 40% less than half-size.)

Example. Take the conditions of the preceding example (p. 64). Basic rate per sq. ft. at 1-in. aperture for an eccentric-driven machine is, from Table 49, 10.7 tons per hr. Under the conditions imposed, $V = 1.2$; E (for 95% efficiency) $= 0.75$; $H = 1.2$; $m = 1.0$ (Table 50). Then $T_{T_{act.}} = 10.7 \times 1.2 \times 0.75 \times 1.2 = 11.6$ tons per hr. per sq. ft. $A = 250/11.6 = 21.5$, which can be handled by a 4 × 6-ft. screen.

Allis-Chalmers uses the total-feed method for eccentric-driven (Aero-Vibe) and for unbalanced-pulley (Low-head) mechanical screens, as well as for the magnetically vibrated (Utah) type. Basic capacity in tons per sq. ft. per hr. is taken from Fig. 57. Factors are applied as in Table 51.

Table 51. Factors modifying capacity of vibrating screens (*Allis-Chalmers*)

Percentages, *a*	Oversize factor, *V*	Half-size factor, *H*	Condition factors, *K* (Based on struck-volume weight of 100 lb. per cu. ft. as fed to screen)

a Oversize in feed; percentage on whole feed less than half-size of the separating aperture.

Example. Take the conditions of the preceding example (p. 64). Basic rate per sq. ft. at 1-in. aperture, from Fig. 57, is 5.4 tons per sq. ft. per hr. Factors, from Table 51, are: $V = 1.03$, $H = 1.20$, $K = 1.25$. $T_{T_{act.}} = 5.4 \times 1.03 \times 1.20 \times 1.25 = 8.4$ tons per sq. ft. per hr. $A = 250/8.4 = 30$ sq. ft., indicating a 4×8-ft. screen.

Stephens-Adamson publish (*Bul "The Vibrator Screen," 4/3/35*) the following approximate short form of total-feed equation for eccentric-driven screens: $A = TB/WQ$ in which T = tons total feed per hr., B is a basic capacity factor of 20 for square apertures or 13 for rectangular apertures, W is wt. per cu. ft. of struck volume in lb., Q is aperture in in. (width for rectangular mesh), and A is screen area in sq. ft.

Example. Applied to the conditions of the preceding example $A = (250 \times 20)/(100 \times 1) = 50$ sq. ft., or a 5×10-ft. screen.

Other Factors

Percentage of opening in the screen covering is usually taken as a linear factor in capacity, *i.e.*, capacity as estimated by any of the methods should be multiplied by the ratio of percentage opening of the screen selected to that of screen of the open area shown, *e.g.*, in Table 49.

Shape of opening also affects capacity. Ordinary rectangular screen with dry ore should be given a factor of about 1.1 in addition to that assigned for increased percentage of opening. For rectangular openings where length/width >6 Allis-Chalmers recommend a factor of 2.0 for dry feed. On moist ore the long rectangular openings may often warrant a factor of 1.5 and surfaces like Rod-deck or unsupported wedge-wire may need a factor of 2.0 or more.

Distribution of feed across the deck is essential. If this is not accomplished by the feeder, deck space is wasted until natural flow effects distribution. This occurs relatively slowly unless the covering is bridged along the centerline.

Intensity of vibration. The effect is suggested in Fig. 55. No other attempt at quantification is known to the author.

Comparison of methods. It is apparent from the screen sizes obtained by application of the various methods, ranging from 18 to 60 sq. ft. of one-deck surface, that either the experiences of the different engineers have been markedly different or the manufacturers are displaying widely separated degrees of conservatism. Published performance data are not of much help in deciding between the various formulas and factors for the reason that information as to nearness of approach to full capacity and as to moisture conditions in the mills is not generally available. Tonnages per hr. per sq. ft. as reported from concentrating plants are in general less than half of the most conservative of the formula figures, but performances are reported that exceed the highest. The question is important in closed-circuit work since overload on the screen is cumulative and soon floods a circuit. This is the probable explanation of the apparent light loads in practice. Since they represent majority opinion of a considerable number of independent engineers they must be given weight.

Capacity in scalping service is usually taken as much greater than where close sizing is desired because, being open-circuit, there is no danger of build-up. Sinden suggests the overflow-type formula $T_L = DMSW/400$ where T_L = allowable total feed in tons per hr., D = depth of layer at feed end, in.; M = width of screen in ft., S = rate of travel along screen, f.p.m.; W = weight in lb. per cu. ft. of struck volume. D may be taken as 2 to 3 times the mean diameter of oversize, *i.e.* (limiting size + aperture)/2. S may be 150 to 250 f.p.m. Load must be lively enough to permit stratification. Length should be from 1.5 times to twice width.

The contribution of size of aperture in this formula would seem to be too small, appearing as it does only as a part of D. It is suggested that the addition of G (= aperture in in.) to the numerator of the equation and an experimental coefficient K to the denominator would make it more useful.

Capacity of multiple-deck screens. A screen analysis of feed is essential. Knowing the rate of feed to the top deck, the respective tonnages over and through each of the decks (with given apertures) may be approximated by inspecting the size analysis of the feed. To determine the net capacity and the area required for a lower deck, recalculate the analysis of the undersize from an upper deck to 100% basis and consider this as feed to the next deck.

In any vibrating screen, the actual effective area is somewhat less than the product of its nominal dimensions (allowing for aprons, side plates, reinforcing bars, lack of distribution, etc.), and in almost all multiple-deck screens the upper end of a lower deck is usually loaded lightly, if at all. Effective screening areas on second and third decks are usually estimated at 90% and 75 to 80% respectively of the area of the top deck.

Example. A three-deck screen with apertures indicated in Fig. 58 is to treat 100 tons per hr. of dry material weighing 100 lb. per cu. ft. (K = 1.0) and sized as in Fig. 59. Distribution of tonnage (Fig. 58) is read directly from Fig. 59. UPPER DECK: From Fig. 57, basic capacity at 1.5-in. opening is 6.5

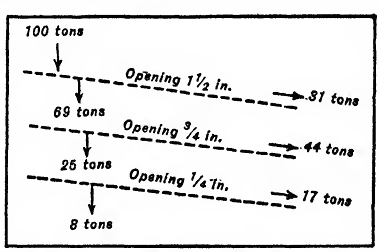

FIG. 58. Capacity analysis for three-deck vibrating screen.

tons per hr. Analysis shows 31% oversize, whence (Table 51) V = 1.04; also, 25% of <3/4-in. (half-size), whence H = 0.70. Hence $T_{T_{act.}}$ = 6.5 × 1.04 × 0.70 × 1.0 = 4.73, and A = 21.1 sq. ft. for feed of 100 tons per hr. MIDDLE DECK: As feed to this deck is only 69% of the original, its proportion of 1 1/2~3/4-in. is (69 − 25)/0.69 = 63.8%, whence V = 1.40. Similarly, the proportion of <3/8-in. (half-size) is 11/0.69 = 16%, whence H = 0.51. T_T (Fig. 57) at 3/4-in. is 4.7 tons per hr., whence $T_{T_{act.}}$ = 4.7 × 1.4 × 0.51 × 1.0 = 3.36, and to treat 69 tons per hr., required area is 69/3.36 = 20.5 sq. ft. Dividing by second-deck factor of 0.9 gives 22.7 sq. ft. BOTTOM DECK: Oversize in feed to this deck amounts to (25 − 8)/0.25 = 68%, whence V = 1.5. Half-size (<1/8-in.) constitutes 5/0.25 = 20%, for which H = 0.60. At 1/4-in. aperture, T_T = 2.3, whence $T_{T_{act.}}$ = 2.3 × 1.5 × 0.60 × 1.0 = 2.07 tons per hr., and A = 25/2.07 = 12.1 sq. ft. Applying the third-deck factor 0.75 this becomes 16 sq. ft. The controlling surface is the second deck. A 4×6-ft. screen will serve.

Lubrication. The bearings of closed-path mechanical vibrators are under heavy high-speed loads and require the best lubrication available. Before a vibrator is started in operation the manufacturer or a lubrication engineer experienced with this type of machinery should be consulted as to proper lubricants and methods of use.

Choice of a vibrating screen. Judging from practice, either heavy impact-type or eccentric-driven machines predominate greatly for screening at meshes down to 1 in. and maintain predominance down to $^1/_2$ in. The impact machine is by far the cheaper; the eccentric-driven machines are better mechanically than any competing machine of impact type. Magnetic machines predominate for fine screening, say 6-m. down, but a part of this predominance is due to the fact that an efficient form, of good design, widely advertised, efficiently sold, and well serviced, has been in the field for many years. Many of the

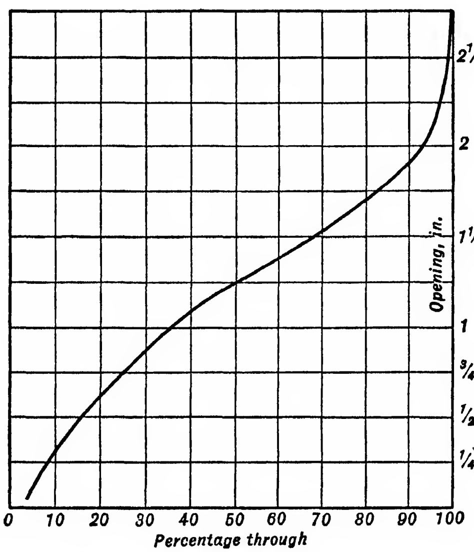

FIG. 59. Sizing analysis of feed for 3-deck screen calculations.

modern forms of unbalanced-pulley machines do good work in fine screening, they are cheaper in first cost, and the designs are improving steadily. In the intermediate field this type is being adopted rapidly.

The primary factor in choice of any screen in an ore-treatment plant is dependability. Operating costs are normally low and first costs are relatively low unless screening is a major part of the treatment schemes. But the screen is usually an important guard for one or more other machines or operations; normally the entire mill tonnage must pass through its meshes, and when it fails to function properly, or stops, the entire mill operation is affected. Hence choice should be checked and double checked against experience, and should lean toward tried and tested forms.

10. TRAVELING-BELT SCREENS

Callow traveling-belt screen (Fig. 60) is typical of this class. It consists essentially of an endless screen cloth *a* passing over rollers *b* so mounted that the upper surface is substantially horizontal. Rubber edgings are buttoned to the screen cloth to keep material on the screen. Feed is distributed over the width of the belt by means of a distributor, pulp is washed by sprays from box *e*, undersize is carried away in chute *f* and oversize carried over the tail roller is washed off by spray from box *g* and discharged through chute *h*. The standard duplex has two belts, each 2 ft. wide and 4 ft. center-to-center of rollers. The simplex has a single belt of same size. The usual speed is between 50 and 100 ft. per min., the lower speed for 8- to 20-m. screening, the higher for 100- to 120-m. Tearing of screen cloth due to recurrent bending around the pulleys is the usual cause of failure, rather than

Capacity is about 4 tons per sq. ft. of total screen surface per 24 hr. per mm. aperture. See Table 52.

Table 52. Performance of Callow screen (*After Cox, Gibbons and Porter, 14 CMI 526*)

Test number	Screen, aperture, mm.	Feed rate, tons per foot of width per hour	Feed rate, tons per square foot per 24 hr. per mm. *b*	Belt speed, feet per minute	Consistency of feed, per cent. solids	Undersize in feed, per cent.	Undersize in oversize, per cent.	Efficiency, per cent. *a*

a By recovery formula (Art. 2). *b* Of total screen surface.

Water required is 12 to 20 g.p.m. per duplex screen for 40- to 80-m. screening; it is somewhat lower at coarse sizes and higher at fine.

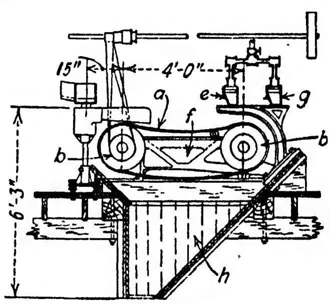

FIG. 60. Callow traveling-belt screen.

At MIAMI COPPER CO., prior to 1918, standard duplex screens equipped with 0.029-in. (0.74-mm.) rectangular-mesh cloth averaged 333 tons per screen per 24 hr. and for a month at a time handled as high as 435 tons per 24 hr. The pulp contained about 67% solids and no spray water was added. This is at the rate of 20.3 tons per 24 hr. per sq. ft. per mm. About 20% of the feed passed through the screen. Efficiency was about 60%.

The tests of Cox, Gibbons, and Porter (Table 52) seem to indicate that the efficiency of the screen is greater at 60- and 100-m. than at 20-, 30- and 40-m.; but the tests on the coarse screens were all run with relatively high percentages of solid and tests 7 to 10 inclusive indicate that dense pulps screen much less readily than thin pulps. It is probable that the difference in consistency explains the apparently discrepant drop in capacity per square foot per millimeter on the coarser screens. Tests 16 and 17 indicate that 65 ft. per min. is too low belt speed for 20-m. screening.

The NEVADA-MASSACHUSETTS Co. employs Callow screens at both of its mills as sole means of preparing scheelite ore for table concentration. At Mill City, Nev. (*IC 6280*), with a mill-feed rate averaging 5.7 tons per hr., one 14-m. duplex screen moving 50 ft. per min. received the undersize of a trommel with $1/8 \times 1/4$-in. Ton-Cap cloth, plus its own oversize circulating through rolls. Undersize of the first Callow (the entire mill feed) passed to a second duplex with 22-m. cloth, moving 75 ft. per min. The third screen, a simplex, with 48-m. cloth moving 75 ft. per min., subdivided the undersize from No. 2. At the SILVER DIKE mill (*IC 6604*), with a mill-feed rate averaging 1.5 tons per hr., a simplex with 12-m. cloth moving 70 ft. per min. treated undersize from a 1/4-in. trommel, plus its own oversize circulating through rolls. Undersize of this Callow (the whole mill feed) was subdivided on a second simplex with 22-m. cloth moving 60 ft. per min.

Each of the three units in the MAGMA mill has a Callow duplex 14-m. screen in closed circuit with Marcy ball mill, passing 250 tons of undersize per day to tables, and circulating 125 tons additional load (Q). Rate of travel, 110 ft. per min.; feed contains 40% water, and 360 gal. wash water per hr. are supplied. The bronze Ton-Cap screen lasts 90 days, and one man can replace it in 5 min. Blinding is practically absent. Efficiency in removal of undersize, 89%. Table 53 gives size analyses of feed and products of these screens as operating in 1930 (*IC 6319*), at which time they were equipped with 12-m. cloth and each passed 260 tons of undersize from a total load of 364 tons per day.

SECTION 8

CLASSIFICATION WITH WATER

REVISED AS TO DORR APPARATUS IN COLLABORATION WITH THE ENGINEERS OF THE DORR CO.

1. PRINCIPLES OF WET CLASSIFICATION

CLASSIFICATION, generally, is an operation in which a mass of grains of mixed sizes and different specific gravities is allowed or caused to settle through a fluid which may be either in motion or substantially at rest. SORTING is another name for the same operation. The fluid ordinarily employed is water, but other liquids, and air or other gases may be used.

Wet classification is used principally in ore dressing and hydrometallurgy. The usual ends served are: (*a*) To effect separation of sands from slimes, or of coarse sands or fine gravels from finer sands and slimes; in general there is no demand in this separation for differentiation on the basis of specific gravity of the grains, but more or less of such differentiation does occur. (*b*) To separate a long-range sand containing grains of different specific gravities into lots (SORTS or GRADES) characterized by the fact that the heavier grains in a given grade are smaller than the light grains. (*c*) To sort a long-range sand composed of grains of substantially the same specific gravities into a number of short-range grades.

General laws of wet classification

1. The relative settling velocities of particles of the same specific gravity and the same shape in a given liquid are dependent upon the sizes of the particles, the larger (and heavier) settling the more rapidly.

2. If particles are of the same size and shape but of different specific gravities, they settle at different rates proportional to their specific gravities.

3. If particles are of the same weight but of different shapes, their settling velocities will probably differ; the particles most nearly spherical will fall most rapidly; those most tabular, most slowly.

4. Resistance to fall in a given liquid is dependent upon the velocity of the falling particle. Resistance varies directly as the velocity when the latter is low, as the square of the velocity when the velocity is high, and as some intermediate power or powers in the transition range.

5. Velocity of fall in a given liquid, all other things being equal, varies as the squares of the diameters of the particles when these are very small, as the $^1/_2$-power of the diameters when the particles are relatively large, and as an intermediate power or powers in the transition range.

6. Resistance to fall increases with the density of the liquid.

7. Resistance to fall increases with the viscosity of the liquid. This increase is relatively greater the smaller the particle.

Formulas for falling bodies. When a body falls in a vacuum under the influence of gravity alone, its velocity v at any distance h from the starting point is given by the equa-

tion $v = \sqrt{2gh}$, g being the acceleration due to gravity. Inspection of the equation shows that the velocity at any point is dependent upon the distance from the starting point alone. When the body falls in a liquid medium, it encounters a resistance which is a function of its velocity; the velocity increases until the resisting force equals the gravitational pull; thereafter the particle falls at this constant (terminal) velocity.

The nature of the resistance differs according to the velocity of the body. When velocity is low, no considerable disturbance is set up in the body of liquid by the passage of the particle; the film or layer of liquid in contact with the particle moves with it while the body of liquid a short distance away is at rest. Substantially all of the resistance to movement is due to the viscosity of the liquid. Such resistance is called VISCOUS RESISTANCE. When the velocity of the body is high, the principal resistance is that offered by the liquid to bodily displacement from the path of the particles. The kinetic energy imparted to the liquid displaced is dissipated in eddying and turbulence. The effect of viscosity is relatively small. The resistance is called EDDYING RESISTANCE and TURBULENT RESISTANCE. At both high and low velocities of fall acceleration decreases rapidly and the body quickly attains uniform terminal velocity.

For spherical bodies Stokes' law for viscous resistance (*9 Pt II Trans. Camb. Phil. Soc. 51*) is:

$$R = 3\pi D\eta V \tag{1}$$

Newton's law for turbulent resistance (*Mathematical Principles of Natural Philosophy, Book II*) is

$$R = K\rho D^2V^2 \tag{2}$$

where R = resistance of the medium, η its viscosity and ρ its density; D = diameter of sphere and V its velocity with respect to the medium. These equations accord with experimental results through certain low and high ranges respectively, but in the intermediate range in which most wet classification is done, neither fits the facts.

Castleman function. Castleman (*Tech. Note 231 NACA*) showed that the experimental data on the fall of spheres in various fluids correlate throughout the Stokes and Newton and intermediate ranges if the results are plotted in terms of the dimensionless resistance function S, of the form

$$S = 2gD(\delta - \rho)/3\rho V^2 \tag{3}$$

in which g is the gravitational constant, and δ is the specific gravity of the solid. He showed that $S = f(N)$, where N is the Reynolds number (*174 Phil. Trans. Roy. Soc. Lond. 935*), which is related to the properties of the system by the equation

$$N = DV\rho/\eta \tag{4}$$

For purposes of use the relationships of Eqs. 3 and 4 are combined in the form

$$T = N^2S = 2g\rho D^3(\delta - \rho)/3\eta^2 \tag{5}$$

The value of T in terms of N is plotted in Fig. 1, in which D is cm., V is cm. per sec., and η is the coefficient of viscosity.

Use of Fig. 1. To find the falling velocity of a sphere under the influence of gravity alone, with respect to any surrounding medium, substitute the values for D, δ, ρ, and η in Eq. 5 and solve for T; read the corresponding value of N from the chart; then solve for V in Eq. 4.

The force of gravity F acting on a sphere submerged in any fluid is

$$F = 1/6g\pi D^3(\delta - \rho) \tag{6}$$

At equilibrium velocity, when Stokes' law applies, R (Eq. 1) $= F$, whence

$$V = gD^2(\delta - \rho)/18\eta \tag{7}$$

From Eqs. 4, 5, and 7 it follows that the relation between T and N in the Stokes range is

$$T = 12N \tag{8}$$

Similarly, when terminal velocity has been reached and Newton's law applies, R(Eq. 2) $= F$, and

$$V = \sqrt{g\pi D(\delta - \rho)/6K\rho} \tag{9}$$

From Eqs. 4, 5, and 9 it follows that the relation between T and N in the Newton range is

$$T \propto N^2 \tag{10}$$

The curves for Eqs. 8 and 10 are plotted on Fig. 1. Stokes' law begins to deviate from the experimental curve at a point somewhat below $N = 0.4$, which, for a quartz sphere in water, corresponds to about 0.074 mm. diameter or 200-m. Newton's law begins to coincide again with the experimental curve about where $N = 3.5 \times 10^3$; corresponding diameter of a quartz sphere is 12.7 mm. Thus throughout the range in which most wet classification is done, neither of the rational formulas holds, and no satisfactory formula for this range has been devised. Fig. 1, however, embraces all of the known and

unknown forces involved in the settling of single spheres in any homogeneous fluid under the influence of gravity alone and may be used for estimating behaviors under conditions approximating this. A similar curve may be drawn for a driving force other than gravity, by suitable modification of force factor g in Eq. 5.

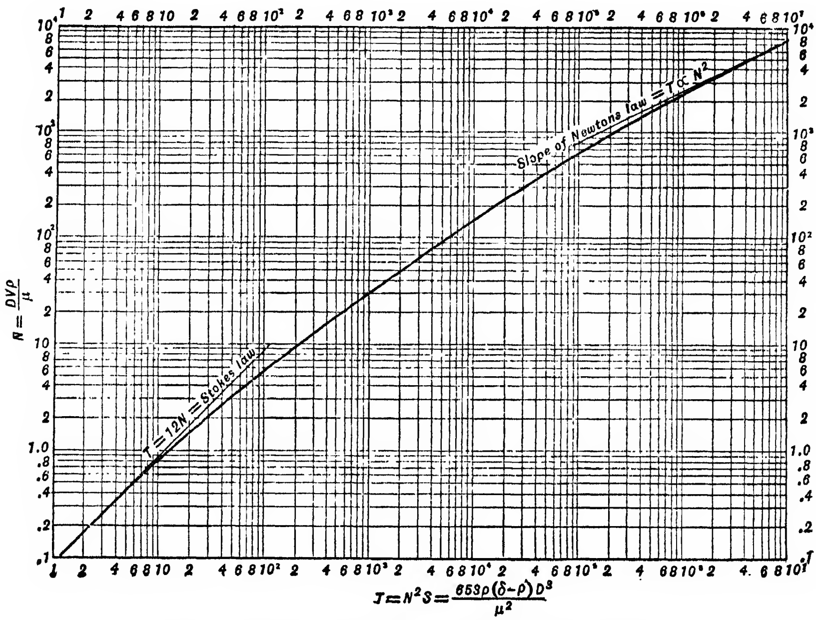

FIG. 1. Reynolds number *vs.* Castleman function for spheres.

Effect of shape. Settling velocities of mineral fragments in water depart considerably from those of spheres (Fig. 2). The cause for the difference is the difference in shape. Waddell (*5 Phys. 281; 217 JFI 459*) has shown, as indicated from Fig. 2, that the settling velocities of particles of a given geometrical shape fall on smooth curves generally parallel to the full curves of Fig. 2, but always below the curve of corresponding specific gravity, by an amount that increases with decrease in sphericity factor (ψ = ratio of surface of a sphere of the same volume as the particle to the surface of the particle) and with increase in size of particle (see Sec. 19, Fig. 134, Table 50). Equiaxed particles smaller than 0.8 mm. in diameter (20-m.) fall at rates closely enough to those of the curves of Fig. 2 to make such curves safe to use for estimation of settling rates of fastest particles of a given specific gravity under free-settling conditions.

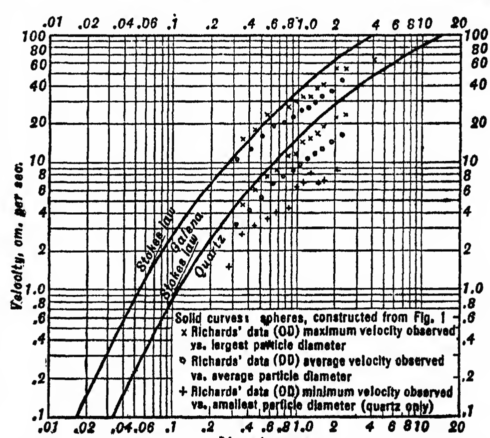

FIG. 2. Terminal velocities of quartz and galena free-settling in water at 20° C.

Hindered settling. Fig. 2 applies only to particles settling individually in bodies of water large with respect to the particles (FREE-SETTLING). If the diameter of the liquid column is less than ten times the diameter of the particle, the settling velocity decreases by reason of a so-called WALL EFFECT which, however, is of negligible importance in commercial apparatus.

A much more potent decrease in settling rate is brought about by the presence of other particles in the settling medium. When the number of these is great enough so that collision between particles occurs or is only near-missed (HINDERED SETTLING), settling rates decrease markedly below free-settling figures. The extent of decrease in falling rate is greater the heavier the particle, the smaller its diameter, the smaller its sphericity factor, the greater the extent of crowding, and the greater the tendency of particles to clump.

0.070	....	28	....	....	....	....

Table 1 shows the effects of specific gravity and of grain size. It is consistent for all three minerals as to the effect of grain size. It is consistent as to specific gravity when comparison is made with quartz, but as between galena and blende, the decrease at any given grain size is greater for blende than for galena. This indicates that the sphericity factor for blende is sufficiently smaller than that for galena to cause this factor to predominate in the reduction in settling velocity.

Hindered-settling effects do not arise in well-dispersed ore pulps of the usual specific gravities, at the sizes normally subjected to classification, when the percentage of solids by

1.97	0.58	180.57	180.5	3.70	

weight is less than about 15. Hence Figs. 1 and 2 may be used for estimating fastest rates in such pulps. For higher pulp densities, in the absence of plastic effects, the curves may be used for approximations by using for ρ the value of the specific gravity of the pulp in the settling zone and by increasing η in proportion to the volumetric percentage of solids. The extent of justifiable confidence in the result decreases, however, at a somewhat greater rate than the assumed value of η increases.

Free-settling ratio of any two minerals is the ratio of the diameter of light-mineral grain to that of the heavy-mineral grain that is equal-settling with it under given free-settling conditions.

Free-settling ratios for spheres may be estimated for any two pure minerals on the basis of the diameters corresponding to a given velocity in Fig. 1. Ratios for actual particles may be estimated by modifying the settling relationships for spheres for shape according to the indications of Fig. 2. Actual ratios exceed those for spheres, except in the finest sizes, as may be inferred from Fig. 2 and as shown in Table 2.

Hindered-settling ratio. Hindered settling prevails in most mill classifiers except those handling the finest sizes. Since the effect of hindrance is greater on light than on heavy particles, it follows that hindered-settling ratios are greater than free-settling. Table 3 gives comparative values for the two ratios as determined by Richards (*41 A 396*).

Hancock (*63 #1 MM 16*) states that for short-range sands in teeter $y = ae^{-bV}$, where y = % solids by volume in the teetering sands, V = velocity of upward current in mm. per sec.; b = a constant for a given sand size, larger for fine sand; e is the Napierian base; and a is a factor, not necessarily the same as y_0, if the latter is the experimentally determined value for the settled sand when current ceases, since this is usually less than would satisfy the equation. For fine rounded sands the agreement between the two is close, but for angular crushed sand the spread is wide. The equation is said to hold for values of y_0 from 20% upward.

Table 3. Free- and hindered-settling ratios of various minerals with respect to quartz

a Anthracite to quartz.

b In one test a quartz-galena hindered-settling ratio of 8.0 was obtained in a small, carefully run experimental classifier.

Utility of equations and ratio tables. As a matter of practical fact, predictions of performance of an actual classifier based on settling equations, curves, and tables are dependable for general order of magnitude only. They are useful in design when applied with generous factors of safety, suitable provisions for adjustment over a wide range, and due pessimism as to the accuracy of the prediction implied.

Character of classified products (SORTS; GRADES). Classified products from a natural ore have two distinct characteristics: (*a*) the grades are of different over-all size range; (*b*) each grade comprises a mass of particles of different shapes, sizes, and specific gravities, so assorted that the largest pieces are the most tabular grains of the lightest mineral; the smallest are the most rounded grains of the heaviest mineral; the intermediate sizes are a heterogeny of rounded grains of light mineral, the flatter grains of heavy mineral, and grains of intermediate specific gravity running the entire gamut of shape.

Purpose of classification in a mill is to utilize one or both of the above stated product characteristics. If sizing is the primary desideratum, if the split is to be made at a size smaller than 10-m., and if a considerable quantity of undersize in the oversize is permissible, a suitable classifier will make the split most cheaply of the apparatus now available, and the undersize will be relatively free of tramp oversize. If gravity concentration is the goal, then, in addition to rough sizing, differentiation by size on the basis of specific gravity is a desideratum in the feed to the concentrator. Such differentiation is attainable only in a classifier. Classifiers are also used for dewatering, desliming, occasionally for concentration of an already sized product, and, in certain special cases (Sec. 10, Art. 7), for concentration by washing.

TYPES OF CLASSIFIERS

Classifiers in a large variety have been designed and built. They may be grouped, however, into two main types on the basis of the direction of flow of the carrying current, *viz.*, horizontal-current classifiers, and vertical-current or hydraulic classifiers. The apparatus

of the first type accentuate the sizing function; those of the second, what may be called the classifying function, *i.e.*, assorting according to size, specific gravity, and shape. Each type has subtypes.

The principal horizontal-current apparatus (mechanical classifiers) have mechanical devices to agitate the pulp and to transport the settled grains away from the separating zone; the others, variously called sand tanks, spitzkasten, sand cones, desliming cones, and the like, are characterized by a tank converging downwardly to a spigot discharge for the settled grains. Horizontal-current classifiers normally, although not necessarily, make two products only.

Hydraulic classifiers are characterized by the utilization of a rising current of extraneous water (hydraulic water) to effect sorting. The principal type, because it does the best work, is the hindered-settling classifier, having a constriction in the sorting column; the free-settling type, without constriction, is rarely used except for the roughest type of work. The hydraulic classifiers are used primarily to separate long-range feeds, 10-m. or less in limiting size, into a number of grades, usually for subsequent gravity concentration. They are also used, to an increasing extent, for fine wet sizing of deslimed, relatively short range feeds composed of minerals with small specific-gravity difference, such as bank sands for concrete work and the like.

MECHANICAL CLASSIFIERS

A mechanical classifier is essentially a settling tank with parallel sides, a vertical or nearly vertical wall at one end, a sloping bottom which extends to a height above the top of the end wall, and a mechanism in the tank which serves both to agitate the pulp therein and to remove the settled solid. The conveying-agitating mechanism may be a reciprocating rake, a spiral, or a flight conveyor (Sec. 18).

The principal use of the mechanical classifier is in closed-circuit wet grinding (Sec. 5, Art. 12). Machines are available to rake as much as 1,000 t.p.d. of sand per ft. of tank width, which satisfies the circulation demand of any present-day grinding mill. Other milling uses are for desliming, dewatering granular material, and washing when scrubbing is unnecessary.

2. RAKE CLASSIFIER

Description. The apparatus comprises a tank, one or more rakes, and a mechanism for actuating the rakes. The tank (Fig. 3) has parallel vertical side walls *a*, a substantially vertical wall *b* at one end, and a sloping bottom *c* of such length that its upper end rises above the level of the top of end wall *b*. The tank is thus capable of holding liquid up to the level of the top of the end wall *b*. The rakes consist of a plurality of parallel blades *e*,

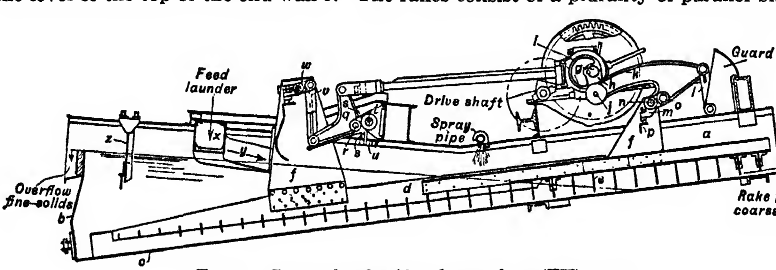

Fig. 3. Dorr rake classifier, heavy-duty (FX) type.

set perpendicular to tank bottom *c* and to the longitudinal axial plane of the tank. They are carried on a frame consisting of two parallel longitudinal members *d*, suitably cross-braced, and hung by plates *f*, two each side, from the actuating mechanism. The mechanism consists of a system of cranks, eccentrics, and links designed to propel the rakes in a path so shaped that each point in each blade describes a rough rectangle with long sides parallel to the bottom and the ends in the planes of the blades. Gear-driven shaft *g* revolves counterclockwise in Fig. 3, causing crank *h* to revolve. Pin *j* in the end of *h* causes the left end of connecting rod *k* to follow. The other end of *k* is pinned to, supported, and constrained by the upper end of link *l*, the lower end of which is pinned to a bearing on the tank. Members *f* are hung by pin *n* on link *m*, which, in turn, is hung on pin *o* on the connecting rod *k*. The lower end of link *m* bears adjustably against angle *p*, which is welded between members *f*. The effect of *p* is to prevent *m* from swinging downward on *o* but to leave *m* free to move upward around *o* under the influence of an upward force on *p*. Eccentric *i* actuates bell crank *q*, which rocks on fulcrum *r* that forms one end

of another angle lever s pivoted on t and actuated by adjusting screw u. The lower end of bell crank q is pinned to the lower end of link v, the upper end of which is pinned to a link w, similar in its action to link m. The motion paths of upper and lower members f are readily traced, and from them the paths of any part of the rake frame. Lift of the rakes is usually about 90 to 95% of the height of the rake blades (see Art. 6, *Speed*).

Feed is introduced and flows thence over a distributing apron toward the high end of the tank. The heavier sands settle into the zone of the rakes and are raked up the slope and out of the tank; slime and the finer sands are carried over the rear wall (OVERFLOW LIP) in suspension.

Rating. Dorr rake classifiers are rated by model designation, which indicates the character of duty for which the classifier is designed, by the width and nominal length of tank, and by the number of rakes, side by side. (See Table 4.)

Table 4. Sizes and types of Dorr rake classifiers

Model No.	Duty	Range of widths, ft.	Range of lengths, ft.
FR.........	Light *a*............	1 1/2 to 4	12 to 23 1/3
FH.........	Intermediate.......	4 to 5	18 1/3 to 30
F..........	Normal *b*..........	6 to 16	18 1/3 to 30
FX.........	Heavy............	5 to 16	24 to 31 1/2

a Corresponds to old model C. *b* Corresponds to old model D.

The number of rakes side by side ranges from one (SIMPLEX) to six (SEXTUPLEX). Normal limit to the nominal width of one rake is 4 ft.; some have been built with 5-ft. rakes.

MODEL F is the standard machine for normal service in grinding circuits. The MODEL FX has deeper rake blades, longer stroke, and a sand-raking capacity 2 1/2 to 3 times that of the standard machine; the tank is extra heavy, the mechanism parts are of cast steel, bearings antifriction and pressure-lubricated. MODEL FR is light weight, suitable for operations in which the rake product is small. MODEL FH is intermediate in ruggedness between F and FR; it is recommended for small closed-circuit operations.

Code. An SSFR is a simplex steel-tank light-duty machine; a QSFX is a quadruplex steel-tank heavy-duty machine.

Tank for ores is usually of steel (S), sometimes of concrete (C); wood (W) and special metals are used for corrosion resistance. The second letter in the rating code signifies tank material.

Rakes are usually of steel, but they may be of wood or special metals for corrosion resistance. Number of rakes is indicated by the first code letter as simplex (S), duplex (D), triplex (T), quadruplex (Q), and sextuplex (Sx).

Manufacturers. Denver Equipment Co., Dorr Co., Morse Bros. Machinery Co., Western Machinery Co.

Data for estimation of capacities of Dorr models are given in Table 5; with suitable consideration for duty, they are applicable to any well-built machines of this type.

Table 5. Capacities (*a*) of standard-duty Dorr F classifier *c*

Mesh of separation	Capacity (*b*), tons dry solid per 24 hr.			Pool area, sq. ft. per ft. of tank width	Rake, strokes per min. *d*	Slope, in. per ft. *e*	Solids in overflow, %
	Sand per ft., of width	Overflow					
		Per ft. of width	Per sq. ft. pool area				
28	320 to 450	130 to 170	9.6 to 11.7	13.55 to 14.55	23 to 32	2 3/4 to 3 1/4	33
35	300 to 400	105 to 145	7.5 to 10.0	14.0 to 14.55	21 to 29	2 3/4 to 3	25
48	260 to 360	85 to 115	6.1 to 7.6	14.0 to 15.2	19 to 26	2 1/2 to 3	22
65	235 to 330	70 to 90	4.8 to 5.9	14.55 to 15.2	17 to 24	2 1/2 to 2 3/4	18
100	210 to 300	50 to 70	3.3 to 4.3	15.2 to 16.0	15 to 21	2 1/4 to 2 1/2	14 to 17
150	150 to 235	35 to 50	2.2 to 2.8	16.0 to 18.0	11 to 17	2 to 2 1/4	9 to 14
200	125 to 200	20 to 30	1.25 to 1.65	16.0 to 18.0	9 to 14	2 to 2 1/4	6 to 10

a Average conditions for ore of 2.70 sp. gr. *b* These figures are safe maxima rather than averages.
c To convert F classifier capacities to other types, multiply the above overflow and sand-raking capacities per foot of width by the following factors:

Slopes and overflow dilutions remain the same. (All types have approximately the same overflow capacity per sq. ft. of pool area.)

Type	Overflow	Sand
FR..............	0.65	0.50
FH..............	0.90	0.85
FX..............	1.25	2.85

d Use slightly higher rake speeds for FR; lower for FX.
e Slope for type FX is 2 1/4 to 2 1/2 in. per ft. for practically all separations; slopes for the other types the same as for F.

Performance data are given in Table 6.

a F = feed, S = sand, O = overflow. b <100-m.

3. SPIRAL CLASSIFIER

Description. The Akins classifier (Fig. 4) comprises an inclined tank *a*, of the same general nature as that of the rake type (Art. 2), and one or two spirals *b* mounted on a through shaft *c* substantially parallel to the tank bottom. The spiral structure effects the necessary agitation in the pool and conveys settled sand up the bottom to the sand-discharge lip *d*. Feed is introduced substantially at pool level, through one or both side walls (*e.g.*, at *h*) at a distance from the overflow weir *e* equal to about one-half pool length. Pool level is maintained as desired by adjusting the height of *e*. Overflow drops into box *f* and is piped away through *g*.

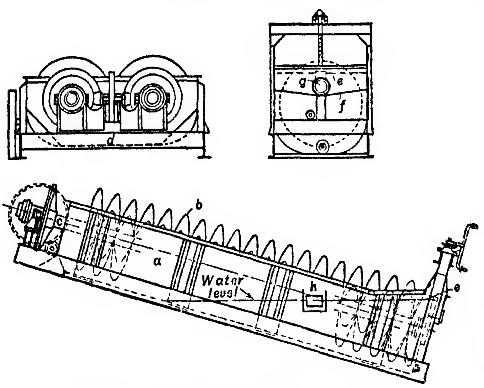

FIG. 4. Akins classifier, high-weir type.

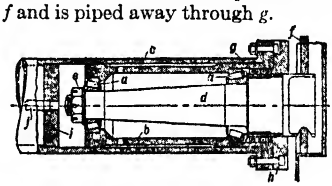

FIG. 5. Lower bearing for Akins classifier.

Tank bottom is rounded as shown. Tank is usually made of steel, but it may be of wood, concrete, or special corrosion-resistant material. The bottom is protected from wear by a sand layer below the reach of the spiral.

Spiral consists of sections of heavy steel ribbon of proper form and width, fastened to the outer ends of arms clamped to the large hollow shaft *c*. The ribbon forms a double-pitch screw. White-iron replaceable shoes protect the ribbon.

Bearings. The upper bearing is swiveled and the bevel drive gear is so arranged as to permit lifting the lower end of the spiral without interference with the drive. All thrust of the spiral is taken against the upper bearing. The LOWER BEARING (Fig. 5) consists of two roller bearings *a* mounted in a carrier *b* bolted inside the lower end of the hollow shaft *c*. A forged-alloy spindle *d*, the outer end of which is squared, is collared in place in the bearing by nut *e* and supported at the outer end in a slot in the hanger *f*. Entry of grit is prevented by packing *g*, held in place by packing flange *h*. The space enclosing the bearing is sealed off from the rest of the shaft by disk *i*, which is pressed in. Grease lubrication is provided for by the pipe *j*, serviced from the drive end.

Adjustment of spiral height. Hanger *f* (Fig. 5) runs in suitable guides and is suspended by rod or chain from a jack screw or worm windlass respectively, either of which may be manually or motor driven. Hydraulic or pneumatic lifts are also available.

Drive. Speed of the spiral shaft is low (3 to 6 r.p.m.) and the drive, therefore, involves considerable gear reduction. Flat-belt, V-belt, chain, and direct drive from a back-geared motor are available.

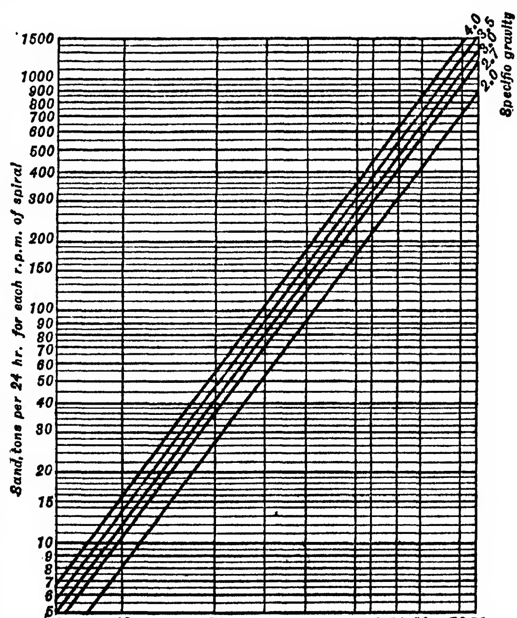

FIG. 6. Approximate sand-raking capacities for Akins simplex classifiers. (Double for duplex.)

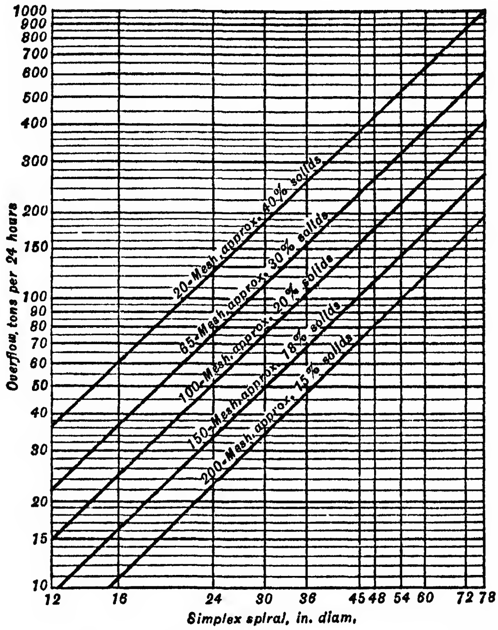
Types. The machine is made in three forms, distinguished by the position of the spiral in the tank. The usual form is the HIGH-WEIR TYPE (Fig. 4), suitable for ordinary



Curves hold for average grinding practice, with classifier sloped about 3 1/2 i.p.f. and solids of 2.7 sp. gr. For other sp. gr. apply factor from Fig. 8.

FIG. 7. Approximate overflow capacities of Akins simplex classifiers, high-weir type. (Double for duplex.)

grinding circuits with separation at 100-m. or coarser and ores that are not extraordinarily slow settling. The SUBMERGED-SPIRAL TYPE has the overflow weir high enough to submerge the lower end of the spiral completely. The area and volume of the pool (and hence the capacity for fine separations) are thus increased; further increase may be effected by widening the tank in the pool portion. In the LOW-WEIR TYPE the lower-end bearing is above pulp level, giving a very small pool area; this apparatus is useful principally for dewatering of granular materials and for rough sand-slime separations.

Size rating is based on the outside diameter of the spiral in inches. Usual sizes are listed as the abscissae of Figs. 6, 7, and 9. The high-weir type is made also in 96- and 108-in. sizes.

Speeds. Recommended maxima are 6 r.p.m. for the 78-in. machines and 20 r.p.m. for the 12-in.

Manufacturer's (Colorado Iron Wks. Co.) **data** for estimation of capacities are given in Figs. 6 to 9.

Performance data are given in Table 7.

Manufacturers. Colorado Iron Wks. Co., Denver Equipment Co.

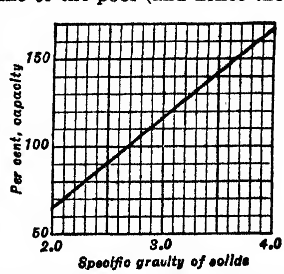


FIG. 8. Factors for use with Figs. 7 and 9.

4. DRAG CLASSIFIER

Esperanza classifier (Fig. 10) is typical of the drag-flight machines. It consists of an endless rubber belt or link chain *a* which carries a plurality of flights *f* and runs on pulleys or sprockets *b* and *c* in an inclined tank *d*. Feed enters the tank at the lower end, fine solids overflow lips or weirs, usually at the side, and sands, after settling, are dragged up the inclined bottom by the flights to the sand-discharge lip at the upper end. In other

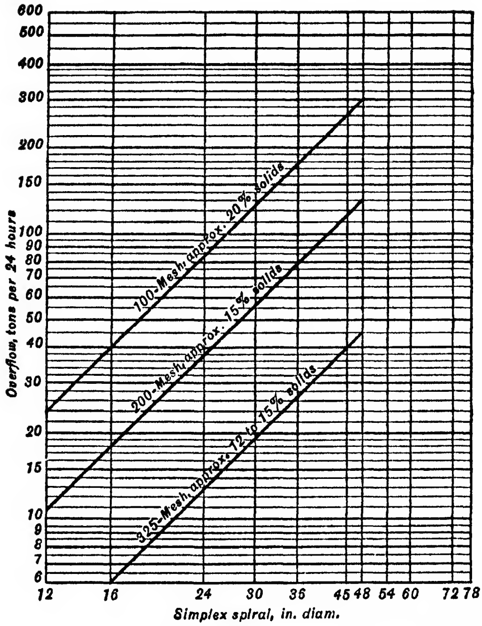
a Reference number from Table 7. b F = feed, S = sand, O = overflow. c <last screen.



Curves hold for average grinding practice, with classifier sloped about 3 1/2 i.p.f. and solids of 2.7 sp. gr. For other sp. gr. apply factor from Fig. 8.

FIG. 9. Approximate overflow capacities of Akins simplex classifiers, submerged-spiral type. (Double for duplex.)

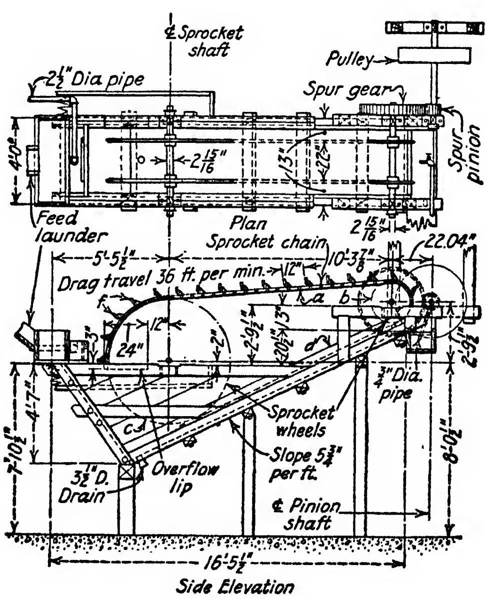


FIG. 10. Drag classifier.

forms, for finer separations, the tank is made wider, with inwardly sloping sides, in the pool area.

Construction, as indicated by Fig. 10, is well within the capacity of any millwright, and the cost is low. A small self-contained unit with steel tank and a welded angle-iron frame is built for dewatering feed to cleaner jigs on dredges; bottom slope is 45°.

Performances are given in Table 8.

Use. On account of the cheapness of construction, many drag classifiers were used in the mills in the early 1920's, when the competing machines were small and relatively inefficient both mechanically and as separators. At present (1943) use is generally restricted to small mills or to crude separations that do not justify the expense of the manufactured machines.

Drag belt. In a modification of the drag classifier, the sand settles on the drag belt and is carried by it above the pulp surface; slime overflows in the usual fashion. The disturbance is less than in the ordinary type and finer sand is, therefore, collected. At INSPIRATION two 18-in. belts were set side by side in one tank; the distance center to center of head pulleys was 39 ft.; the vertical distance from the overflow lip to the lower run of the belt was 5 ft. The machines were used to separate sand, for tabling, from flotation tailing.

5. HARDINGE COUNTERCURRENT CLASSIFIER

Description. The Hardinge classifier (Fig. 11) consists of an inclined rotating cylindrical drum *a* with a continuous ribbon spiral *b* attached to the interior of the shell, rotation being in such direction with respect to the spiral that material in the spiral trough is impelled toward the higher end. The lower end of the drum is closed by a plate *c* with a central circular overflow opening. The higher end of the shell proper may be completely open, or may carry the sand elevator *d*. The pitch of the spiral decreases gradually from the low to the high end, while the inwardly projecting ribbon decreases gradually in height in the opposite direction. Feed is introduced via an externally supported internally projecting launder *e*, which may enter either end, but preferably the overflow end. The plunge of the feed stream and the movement of the spirals agitates the pulp in the pool sufficiently to maintain a classifying pool through which sand settles and is moved up-slope by the

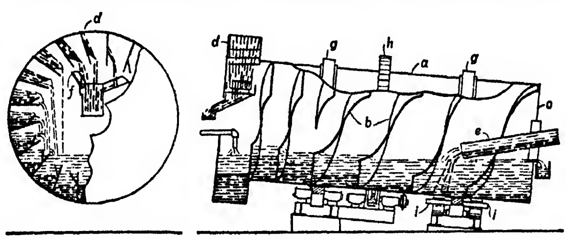

FIG. 11. Hardinge countercurrent classifier.

push of the ribbon. The deeper ribbons near the upper end maintain supplemental pools above the level of the main pool; wash water, introduced at the sand end, flows into and through these pools with sufficient velocity to lift out slimes freed by the working of the sands. The gradual decrease in pitch of the spiral causes increase in depth of the sand bed toward the sand discharge, which has some tendency, in combination with the turnover due to rotation, to work slimes and fine sands to the surface of the bed, where they are exposed to the flow of wash water in the supplemental pools. Introduction of wash water into the sand elevator *d*, as indicated, has some further desliming effect by draining from the flights above water level, and by the agitation caused by the falling drainings. The sand elevator dries the sand more or less, the extent being somewhat controllable by varying the position of sand-receiving shelf *f*.

Shell *a* is built of welded plate, and carries two tires *g* and a girth gear *h*. The tires are supported on rollers, and thrust rollers *i* maintain the tires in position on the slope. Usual DRIVE is by a sprocket on the pinion shaft. The interior of the shell has light LINERS to which the sections of the spiral ribbon are bolted.

Slope ranges from 1/2 to 1 1/2 in. per ft.

Manufacturer's data for estimating capacities are given in Table 9.

Performance data are given in Table 10.

6. OPERATION OF MECHANICAL CLASSIFIERS

The essential elements of a mechanical classifier from the standpoint of operation are the settling tank and the agitating and sand-transporting mechanism. These act jointly to produce the separation effected; hence, while the various structural elements and operating changes of each must be considered separately in determining their effects on performance, it should be borne in mind that at all times constancy of all other elements is implied.

Principle of area. The body of pulp in a mechanical classifier is divided into several zones having different particle-size and pulp-density characteristics. The inclined-trough apparatus, shown diagrammatically in Fig. 12, may be taken as typical. Zone A, on the bottom, is a layer of inactive stationary sand, the first to settle after the classifier started operation, below the lowest reach of the sand-removing mechanism, and serving simply to protect the bottom of the tank; it takes no part in the classifying action. Zone B, comprising the material lying in the space swept by the sand flights in their sand-propulsive movement, is the material that will be delivered as rake product, excluding a small amount of fines that will be disengaged by turnover and by the action of spray water; it likewise is finished so far as classification in the pool is concerned. Zone C is a quicksand, *i.e.*, a suspension of sand in water, maintained by agitating, having a buoyant effect analogous to that of a liquid of the same composite density (weight of included sand plus water divided by volume), but subject to rearrangement of particles within itself on the basis of their weight, so that particle size and pulp density increase from top to bottom (Table 11). This zone is of substantially constant volume but of ever renewing solid content in a classifier operating properly under constant feed conditions; new material of the same character as respects particle size and specific gravity replaces the material that settles out of the bottom into zone B; momentary increase in depth by piling up at the top tends to decrease the activity of and compact the bottom whereupon the settling rate of the bottom particles into zone B is increased and the condition tends to correct itself.

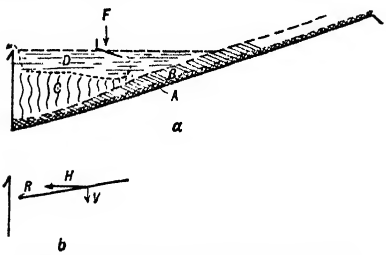

FIG. 12. Zones in a mechanical classifier.

a 6-ft. duplex normal-duty machine operating with 320 t.p.d. of feed and 1,100 t.p.d. of sand; 21 s.p m.; slope, 2 3/4 in. per ft.
b Overflow about the same density.

Zone D comprises essentially a stream of pulp flowing horizontally across the top of zone C from feed apron to overflow weir. During this travel the solids settle so that the average path of any given particle, relative to the tank, is diagonally downward, as R in Fig. 12, item b, the impelling forces being gravity and the horizontal impulsion of the stream. If the velocity components of R are taken as H and V respectively, b is the breadth of the tank, d the depth of zone D, l the distance from feed point to overflow, and Q the total volume of pulp flowing per unit of time, then $H = Q/bd$.

If a particle reaches the bottom of zone D, *i.e.*, gets out of the stream before it reaches a point near the weir where a relatively strong rising current exists, it will not overflow. The limiting condition is when it just fails to enter zone C. This condition is expressed as $d/V_c = l/H$, whence $V_c = Hd/l = Q/bl$. But V is some direct function of D, where D is diameter of particle (Fig. 2), and bl is the area of pool. Thus it follows that D_c, the largest particle in the overflow, varies inversely as the area of the pool for any given volume of pulp flowing. The effects of changes in structure and operating conditions are all to be examined against the background of this principle of area.

Slope of tank bottom determines pool area, sand-raking capacity, and sand drainage, all other conditions remaining constant. It thereby affects mesh of separation and moisture

content of sand discharge, and it may have serious effects on the stability of classifier operation (see *Surging*). The effect on pool area may be and is compensated by change in height of weir or by baffle placing, so as to maintain area an independent factor in the operation. Drainage effect increases, of course, with increase of slope to produce drier sand.

Maximum slope is determined by the tendency of sand to slip back into the pool. The critical point in slip-back is where the sand load emerges from the pool, since this is the point of maximum disturbance of the load by the water; once the sand gets beyond this point it will discharge except for small amounts of fines carried back by drain or spray water.

Tendency to slip back is dependent upon size, specific gravity, shape, and surface texture of the sand particles and upon the presence of clayey or talcy slimes in the feed material. The question resolves primarily on the angle of repose of the settled material and its tendency to pack. Coarse, jagged, and rough-surfaced particles have a high repose angle and can stand steep slopes; particles of high specific gravity tend to pack and thereby enhance their resistance to swash at the vee of the pool; it is the apparent rather than the real specific gravity that is important. Slimes, particularly those of a slippery nature, act as lubricants and reduce repose angle. Long-range sands require flatter slopes than short-range.

Clean sand. When maximum cleanliness of sand product is desired, a strong spray is directed at the solid load as it emerges at the vee. Since this tends to increase tendency to slip back, but is essential to disengagement of fines, slope must usually be decreased.

Surging is a cyclic variation in tonnage and character of sand and overflow. It occurs when sand-raking capacity is inadequate or pulp in the pool is too dense. Cycles usually range in length from 10 to 20 min. They are characterized by a gradual decrease in tonnage of sand raked and an increase in its size. There is no corresponding change, at the time, in tonnage or character of overflow. Hence a selective building up of intermediate sizes in the pool occurs. The top of zone C, Fig. 12, rises. When the top of zone C has almost reached the surface of the pool (probably has reached it in effect), and the rake load has virtually disappeared, overflow suddenly becomes much coarser and the classifier unloads over the weir. Thereupon the pool becomes overly dilute, rapid settling occurs, the rakes are again overloaded, and the cycle repeats.

Remedies for surging are (*a*) ample sand-raking capacity and/or (*b*) dilution. Raking capacity may be built into the classifier, or increased, if otherwise inadequate, by increasing speed or the area of submerged parts. When increase in sand capacity is accompanied by increase in agitation, the pulp must be diluted in order to prevent increase in suspension and correspondingly coarser overflow. Steeper slopes may be used on light-duty rake classifiers than on heavy-duty because the light machines operate with shorter strokes, which cause less agitation.

Slopes for rake classifiers fall in the range of 2 to 3 1/2 in. per ft. Spiral classifiers operate with less agitation and without any release of push on the sand load; they may, therefore, operate on steeper slopes, and, since maximum possible elevation of the sand is usually desirable in closed circuits, slopes on normal ores are ordinarily in the range of 3 to 4 in. per ft. Actually the slope is steeper than this because the sand is lifted somewhat up one side of the curved bottom of the tank. Drag classifiers operate on yet steeper tank slopes, up to 6 in. per ft. The corresponding slope of the Hardinge classifier is not that of the axis of the drum, but rather that of the spiral trough as it emerges from the pool; it, therefore, varies throughout the length of the cylinder with the variable pitch of the spiral, and is further dependent upon diameter of drum, height of overflow, height of spiral ribbon, and slope of drum axis. There are not enough data available to state its magnitude; it should be possible to work with higher actual slopes than in the other types because of comparatively smaller disturbance in the vee. On the other hand, elevation of sand at the end of the classifier cylinder is always necessary in a closed circuit because of the flat slope of the cylinder itself.

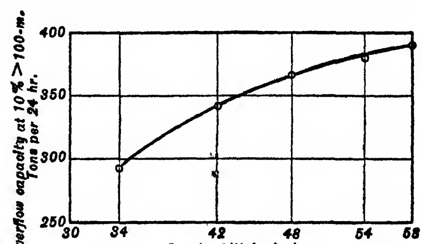

FIG. 12A. Effect of weir height on capacity of Dorr rake classifier.

The Dorr Company recommends that slopes be as flat as possible when sharpness of separation is the primary desideratum.

Height of overflow is an operating variable in some types of mechanical classifiers (Akins, Dorr heavy-duty) and change is not a major structural operation in the others. Adjustability adds greatly to the flexibility of the machine, however, particularly when density of overflow is fixed by and must be maintained to satisfy subsequent treatment requirements. Change varies the area of the pool; increase decreases the intensity of surface agitation in the region of the overflow lip but not at the vee. High weirs are used for fine separation both because the large pool is needed ($D_c \propto 1/a$, p. 22), and because the decreased agitation reduces pulp density at overflow level, where final separation is made. Conversely,

low weirs are used for coarse separations. Effect of height on character of overflow product is shown in Table 12 and columns 1 *vs.* 3 and 2 *vs.* 4 in Table 13, presenting tests on Dorr classifiers. Height must be less when overflowing solids of high specific gravity than for normal ores. Effect of height on capacity is shown in Fig. 12*A*, which is for a 6×25-ft. normal-duty duplex Dorr classifier working in a closed grinding circuit at Timber Butte; 23 s.p.m.; 20% solids in overflow.

a Height of tailboard increased 3 in.
b Rakes notched with staggered cutouts, 3 in. wide and full depth of vertical flange.

F = Feed.
O = Overflow.
S = Sand.

Height for light-duty Dorr classifiers is 21 to 24 in.; for heavy-duty machines these figures may be more than doubled. In the Akins high-weir machines the depth at right angles to the spiral shaft ranges from 1 in. greater than spiral diameter in small machines to 8 in. less in the 78-in., and 18 in. less in the 96-in. machine; in the submerged-spiral type the height is 1 1/2 to 2 times spiral diameter.

Speed is important from the standpoint of agitation of the pulp in the pool. The effective speed is, therefore, a composite of the velocity and area of the propelling surface, its path, the angle at which it strikes the pulp, and, to a degree, of the place, relative particularly to the overflow weir, in which the propulsive force is applied. The internal-spiral (Hardinge) type has the lowest effective velocity from the standpoint of propulsive force and effect, and this lack is compensated by a relative decrease in depth of pool to bring the disturbance nearer to the surface; the energy of the feed stream and that of the wash water are also utilized for agitation by causing them to plunge into the pool. Little agitation

is caused by the spiral ribbon of the Akins machines, but the radiating arms from the hubs to the bands are steel strips twisted so as to present their broad faces at right angles to the direction of movement through the distance from the hub to the inner edge of the spiral: they thus afford the agitation necessary to effect the desired suspension. In the high-weir type this agitation extends to the surface of the pulp along the centerline of the pool almost to the overflow lip; in the submerged-spiral type it is well below the surface in the region of the overflow. Maximum peripheral speed of the agitating arms is of the order of 60 to 120 f.p.m. Average lineal speed of travel in the reciprocating-rake type machine is in the general range of 20 to 60 lineal f.p.m. for the normal-duty machines, about 80% of this for light duty and double it for heavy duty, corresponding to stroke lengths of 10 to 14 in. for the light- and normal-duty types and 18 to 20 in. for the heavy-duty type. Maximum lineal speeds in cycles are probably double the averages. Blade depths are normally 3 1/2 to 4 1/2 in. for light-duty, about 5 in. for normal-duty (4- to 8-in. range), and 8 to 9 in. for heavy-duty machines. Depth of blades may be decreased below the feed point (toward the overflow) in reciprocating-rake machines in order to decrease agitation in this region; such reduction is permissible from the sand-raking standpoint owing to the smaller amounts of sand in this region. Such decrease is standard design in the heavy-duty machine (Fig. 3), the blade height being decreased gradually from 8 or 9 in. to 1 1/2 or 2 in. Lineal speeds for rakes in bowl-rake classifiers (Art. 7) average 65 to 75% of those of the same type without bowls, and the blades are, in general, somewhat smaller in depth. The drag machines have approximately the same range of flight speeds as the averages for the light- and normal-duty rake types, but this speed is uniform and unidirectional.

Agitation is a maximum in the reciprocating-rake machines, judged from the extent of surface movement both at the vee and at the overflow weir; it is least at the overflow weir in the submerged-spiral type, in bowls operating with low rotary-rake speeds, and in the desliming drags. Relatively strong agitation at the vee is desirable when clean sand is the desideratum, because the last effective cleaning takes place here. Addition of dilution water at this point increases the cleaning. Agitation through the mass of suspended sand in the pool (zone *C*, Fig. 12) is probably most thorough in the submerged-spiral machine; this is helpful with slimy ores that have a tendency to flocculate. In all types agitation is decreased, usually by joint decrease in speed and height of blade as pool area is increased to effect fine separation. Increase in height of overflow has an independent effect on agitation at the overflow, however, because of the corresponding increase in distance from the surface of the pulp to the center of disturbance, and the relative increase in volume of pulp throughout which the energy of the agitator is absorbed. Conversely, the effect of an increase in agitation is the same as a decrease in area of pool. Effect of changing the speed of an 8-ft. FX classifier closing circuit on a 7×10-ft. ball mill crushing porphyry ore is shown in Table 14.

Table 14. Effect of rake speed on products of a rake classifier *a*

675	60.4	13.7	9.1	4.5	0.75	76.6	5.3

a All factors constant except as noted in table. Weir height, 45 in.

Sand-raking capacity varies as the forward speed of the blade and as the square of its height. Maximum capacity does not, however, equal or, in most cases, even closely approach the capacities estimated from simple geometrical considerations. The discrepancy is due to fluidity of the sand, particularly while submerged, to slip-back along the face of spirals, and to slump as support is taken away when reciprocating rakes are lifted. Raking efficiency is increased to some extent by placing the propelling surfaces closer together than simple analysis would indicate; thus the Akins machines use a double-pitch spiral and the Dorr apparatus spaces reciprocating blades at a distance equal to about one-half the stroke length. Actual capacities for sands of usual grinding-circuit sizes for average ores may be estimated from the tables of manufacturer's data and checked by the performance tables in this section; the effects of changes in pitch of spirals or in height and spacing of blades and flights is a matter, almost, of pure conjecture, lacking direct experimental data.

At Compania Minera de Peñoles (*153 A 623*) a rake classifier with insufficient sand-raking capacity was fitted with about 16 @ 1-in. pipes projecting upward through the tank bottom to a level just below the lower edge of the rake blades, spaced so that each drew from substantially equal areas under the entire area of the pond. Screen tests of pipe sands and rake sands were substantially identical. The amount drawn through the pipes was 7 to 8 times the amount raked; solid content was about 80%.

Baffles (item *z*, Fig. 3) are used on rake classifiers when otherwise mixing of the feed with the pool contents is inadequate, and the incoming stream segregates, with the result

that the liquid runs across the pool and overflows without its proper load of solid. This condition occurs most frequently in coarse separations (>20-m.) or with quick-settling ores (*e.g.*, the magnetite-pyrite-chalcopyrite ore at PENNSYLVANIA STEEL Co., Lebanon, Pa.).

The baffle has several effects: it decreases pool area and thus decreases settling rate; it produces rising currents of relatively high velocity and correspondingly increased carrying capacity directly at the overflow; and it directs a flushing current down into the top of zone *C* (Fig. 12) which tends to carry the material thus flushed out on up the restricted channel between the baffle and the tailboard. It thus tends to prevent building up of sand in the pool, and to clean up the rake product; but it also increases the amount of tramp oversize in the overflow.

Baffle is standard equipment on Dorr rake classifiers for normal and heavy duties. It is spaced as much as 24 in. from the weir for fine separations, and as close as 1 1/2 in. for very coarse overflows (*e.g.*, 14-m. at GRAND COULEE DAM). The deeper it extends, the coarser the overflow. It should be adjusted as to submergence and horizontal spacing until the nearest possible approach to the desired separation is achieved.

Width of tank determines directly the sand-raking capacity, all other things being constant. Taken with slope and height of overflow, it determines pool area and, consequently, capacity for a given mesh of separation or, conversely, the mesh of separation for a given feed volume. Hence width is determined by the tonnage of either sand or overflow product, whichever is the greater. In this connection, it must be borne in mind that increase in speed increases both sand-raking and overflow capacity, and that, with a given tonnage of feed, the increase in overflow decreases the tonnage of sand to be raked. Similar increase in overflow capacity may be obtained by increase in pulp density.

Increase in width of tank is usually accompanied by multiplication of sand-propelling units. Such multiplication is normally the result of structural demands, since the weight and cost of large propulsive units usually increase more rapidly than their capacity. But at the same time multiplication yields considerable advantage in respect to the character of the agitation, particularly in the reciprocating-rake machines, since it opposes the impulses and breaks the currents up into small eddies, as opposed to the swashing wave caused by a single rake in the tank.

Widths required for given tonnages of overflow at particular dilutions are given in Table 5 and Figs. 7 and 9 for Dorr and Akins classifiers respectively; no such data are available for other types. Below 10 to 15% solids the question is simply a matter of calculation of pool area from free-settling velocities, except that for very fine separations (*e.g.*, 325-m.) the velocity of cross flow from feed point to weir must be considered, and pool area be made sufficient to permit sand to settle to the rake zone before the accelerated rising current near the weir is reached. At higher densities, settling velocities are affected by the specific gravity of the pulp; data for their estimation are not available. In general, however, the decrease in settling velocity and consequent gain in capacity per unit of area (and width) are greater proportionately than the change in density, as may be seen by inspection of Eqs. 7 and 9, bearing in mind that η increases as ρ increases.

Length of tank is determined in part by the requirements for washing, dewatering, and drainage, but primarily by transport demands. In general, 5 to 8 ft. of drainage deck beyond the point of emergence from the pool is allowed; further length on the same slope is substantially ineffective. Additional drainage can, however, be obtained by a 20- to 30-in. extension of lip on a slope about 5% greater than that of the bottom, with no additional propulsive elements. Sand piles up here and is compacted as the last rake (or spiral), made deeper, pushes it out to the distant lip. Moisture content is 2 to 4% lower with such an arrangement. (See also Sec. 15, Art. 2.)

Further increase in raked length is usually provided in order to elevate sand sufficiently to permit gravity return to a grinding mill. The lengths of the majority of classifiers in grinding circuits are determined by the lengths of the mills on which they close the circuit (Sec. 5, Art. 12).

Feeding. The stream of feed to a classifier has a large amount of kinetic energy and if allowed to plunge directly into the pool it causes considerable agitation, so directed and localized as to carry down into zone *C* (Fig. 12) material which would otherwise not penetrate this zone, but would stream across the top to the overflow. The result is that zone *C* becomes congested (see ***Slope***). Furthermore penetration of zone *C* by the plunging stream stirs sand into the cross stream and increases the amount of tramp oversize. The best method of feeding is to slow the stream down by flowing it over and spreading it on an apron, partially submerged in the pool, and sloped toward the sand-discharge end, so that most of the kinetic energy is absorbed in the part of the pool farthest removed from the overflow. The desirability of this procedure is greater the finer the mesh of separation and the more stringent the requirements as to tramp oversize and cleanliness of rake product. The normal feed point is about one-half of the distance from overflow weir to the vee of the

pool, but with average ores the nearer the point of actual release of sand from the feed tray is to the vee, the better the mixing of sand and water and the less the likelihood of congestion in the classifier. However, if a coarse separation is required, and the feed is slime-free or of high specific gravity, it may be advantageous to feed much nearer the overflow than normal, and even turn the feed tray toward the overflow weir. An even better plan under such circumstances is to design initially for limited area.

Table 15. Effect of dilution on products of a rake classifier handling heavy ore [a]

[a] Tests on a 12-ft. FX Dorr classifier closing circuit on a 6 1/2×15-ft. rod mill grinding high-sulphide ore. Weir depth, 43 in. All operating factors constant except as noted in the table.

[b] This number would have been smaller had tonnage not risen at the same time that pulp density was lowered.

Dilution. The density of the overflow pulp is the most important factor in determining mesh of separation in a classifier that is not overloaded on the fine end. Increased dilution (*i.e.*, decreased sp. gr. of overflow) makes for finer separation with normal ores, and *vice versa*, if the pulp contains more than about 10% solids (see Tables 15 and 15*a*); if the pulp is more dilute and not too clayey, increase in dilution at constant solid tonnage increases rising velocity and makes for coarser separation.

Table 15*a*. Effect of dilution on products of a rake classifier handling light ore [a]

Solids, %	Overflow >65	Overflow >100	Overflow <100	Sands >65	Sands >100	Sands <100
	Cumulative percentages

22	3.1	11.0	89.0	60.5	87.1	12.9

[a] Quartzitic gold ore containing about 6% sulphides. New-feed rate, 225 t.p.d.; <10-m. Normal-duty 6-ft. duplex Dorr classifier; 3 1/4 in. per ft., 23 s.p.m., 40-in. height of weir.

The pulp density at which the change in effects comes is called the CRITICAL DILUTION. Critical dilutions for average ores for different meshes of separation are given in the last column of Table 5. Overflow capacity is a maximum at critical dilution; decrease in dilution slows down the rate at which sand drops out, thereby increasing the time that must be allowed for the surface stream to drop out the small sand particles; increased dilution beyond the critical lowers the concentration of solid per unit volume of cross stream without change in rate of settlement of sand. The effect at UTAH COPPER Co. is shown in Fig. 13.

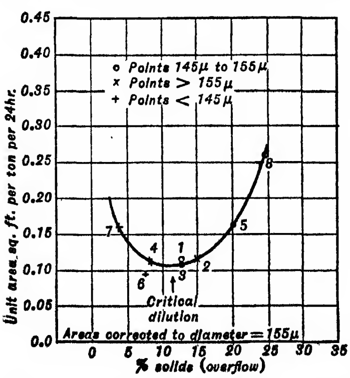

FIG. 13. Dilution *vs.* capacity of rake classifier.

The effect of change in dilution on mesh of separation is much greater for coarse separations than for fine, *i.e.*, at high pulp densities than at low. This fact is reflected in the density tolerances in Table 5. If, by reason of flotation requirements, for example, a classifier is run at a density above critical, the effect is as though the area of the classifier were increased; speed must then be decreased, and as a result fines are less effectively winnowed out in zone *C* (Fig. 12) and more pass into the rake product. Mesh of separation in classifiers operating above critical density is much more sensitive to fluctuations in feed rate than in those at and below, but rate of change of capacity is less on the dense side (Fig. 13).

Water to control dilution is added in the feed launder, in the tank, or onto the sand at or near the vee; in the launder it aids transport and distribution, but increases the stirring effect of the feed; when introduced into the tank it should be sprayed onto the pool surface in order to utilize surface tension to decrease the kinetic effect; at the vee it helps to release slime at the point where the sand is most mobile and responsive to spray washing.

Character of ore. An average ore, from the standpoint of mechanical classification, is one that consists of a relatively unaltered silicate gangue, not more than 5 to 10% of sulphide minerals by weight, a small amount, usually about 2 or 3% or less, of secondary silicates and earthy oxides (primary slimes), and a small amount of soluble salts, mostly sulphates of the heavy metals present. Such an ore, when ground to 20-m. or finer in new mill waters from lake, stream, or well, at the *p*H which falls with such an ore (usually in the range 5.5 to 7.5), is lightly flocculated. Material in zone *C* (Fig. 12) in a classifier treating such an ore is smooth-feeling, has some body but not too much, and is internally mobile under the normal action of the classifier; the solids in zone *D* are not visibly flocculent, but there is normally a very thin layer of clear water on top of the pool; the sands are not harsh to the touch. Addition of normally small amounts of lime or soda ash to the grinding circuit, raising the *p*H to 7 or 8, makes little visible difference in the behavior of the ore in the classifier. The classifier operator says that such an ore contains just the desirable amount of slime for buoyance and lubrication, and not enough sulphide for troublesome quick-settling segregation. When, whether by reason of absence of primary slime in the ore, or because of thorough preliminary desliming, this small amount of slime is absent, it is necessary to run with a smaller pool, higher pulp density, and higher speed; material in zone *C* becomes harsh-feeling and alternates from undue looseness to heavy matting, and the operation becomes sensitive and hard to control. Surging will occur, if sand-raking capacity is not well in excess of normal demands.

If an ore contains large amounts of primary slime, and particularly if this is accompanied by other large amounts of soluble salts produced by oxidation of sulphides, so that *p*H is correspondingly low and lime must be added to the grinding circuit to reduce steel consumption, the slime flocculates badly, the pulp must be kept dilute, and a large pool area must be provided to handle the large volume of water and to permit of slow and careful differentiation between the quick-settling flocs and the only slightly more rapid settling unfinished sand.

Dispersion, when it can be effected, is the best remedy for the difficulties of over-slimy pulps. Sands fall out of well-dispersed dilute pulps almost as rapidly as they do from slime-free pulps. Felting (Sec. 11, Art. 25) is never as bad in dense dispersed pulps as in the same pulps flocculated, and the tendency to felt can be controlled by varying dilution. The result is that the dispersed pulp can be separated to a given mesh in a smaller classifier than would otherwise be necessary and is easy to control.

Effect of excess lime in a slimy feed at CANANEA is shown in Table 16. See also Sec. 5, Art. 12.

Table 16. Effect of lime on performance of a rake classifier at Cananea

Test	1	2	3	4	5	6
Lime, lb. per ton of solution	0.3	0.4	0.77	1.11	1.54	1.80
Feed, % solids	42.5	42.2	42.2	42.2	42.3	42.2
Overflow, % >65-m.	1.64	2.69	3.95	6.62	7.46	14.3

Capacity of a mechanical classifier is limited ultimately by the ability of the sand-transporting mechanism to remove settled material. Pool area must be sufficient to settle out the particles that it is desired to remove at the sand ends. If a reasonable efficiency is demanded, say 40 to 50% with normal ores, pool area is generally the determiner of capacity when the feed contains, say, 65 to 70% of undersize (see ***Principle of area; Dilution***). As percentage of undersize decreases, sand-transport becomes more and more the controlling factor (see ***Width of tank***).

Efficiency. (For method of estimation see Sec. 19, Art. 24.) Efficiencies for rake and spiral classifiers range, in general, from 30 to 60%. Average for 21 rake machines reported was 50% against 35% for 9 spiral machines. Examination of the various elements of the efficiency calculation for the cause of the difference shows that the feeds to the spiral machines averaged 68% of finished material against 64% in the rake feed, which is probably not a significant difference; that the difference in content of finished material in overflow and sand ($c - t$; Eq. 163, Sec. 19) was 48% in the rake machine *vs.* 40% in the spiral; and that the difference between the content of finished material in feed and sand ($f - t$) was 14% in the rake *vs.* 9.7% in the spiral. While the arithmetic form of the efficiency equation is such that efficiency appears to be penalized for increase in $c - t$, this is not the case if there is corresponding increase in $f - t$, *i.e.*, it is the ratio $(f - t)/(c - t)$ that is controlling.

The values of this ratio are 0.29 and 0.24 for the rake and spiral respectively. It should follow, of course, that since the rake makes the comparatively cleaner sand and removes more of the finished material from the feed on a single pass, on the average, the circulating loads in spiral-classifier circuits should average higher than in rake circuits. The averages from Tables 6 and 7 are 250% circulating load for the rake and 350% for the spiral. For the effect of this difference on the grinding circuit see Sec. 5, Art. 12.

The low numerical efficiencies of the mechanical classifiers are not to be taken too seriously. The performances analyzed herein were all for ores in which the valuable minerals are heavier than the gangue. Hence a part of the fine material retained in the sands was heavy mineral which hung back and built up in the sand circuit (Sec. 5, Art. 12). This property of such circuits can be and is turned to advantage in most mills. Minerals that break flat tend to produce tramp oversize and lower efficiency.

Comparison of the efficiencies given in Table 6 (average 50%) with those in Table 40 in *Ed. 1* (average 55% for 20 machines) indicates that such advance as there has been in the rake classifiers in 20 years has not been in efficiency. The present machines are bigger, more rugged, and better mechanically than the old, and the apparent decrease in efficiency is due to heavier loading. In 1923 average tonnage overflowed per 24 hr. per ft. of classifier width was 54 for 23 machines reported against 92 in 1943; corresponding figures for sand raked are 126 and 182. These latter figures reflect the somewhat higher average circulating loads in modern grinding practice; overflows are now crowded as compared with 1923 to save on capital costs.

Power consumption of rake and spiral classifiers is so small in comparison to capacity as to be negligible from the standpoint of operating cost in most cases. Dorr Co. recommends 0.5 to 1 hp. per ft. of width for rake classifiers plus 50% additional to cover starting loads; power for bowl ranges from 1/4 hp. for 4- and 6-ft. diameters to 2 to 5 hp. for 25 and 28-ft. diameters. Colorado Iron Wks. recommends motors on the basis of 2 1/4 hp. per 1,000 daily tons of sand raked in small machines to 1 1/2 hp. for large. Power required per ton for duplex machines is slightly less than that for simplex.

Attendance for classifiers in grinding circuits is a part of the duties of the grinding-mill operator (see Sec. 5).

Maintenance of mechanical classifiers is low. Costs reported from 7 large plants range from 0.1 to 0.4¢ per ton, average 0.3¢. At Cariboo Gold Quartz Mine (*PC*) maintenance cost for a normal-duty Dorr machine in secondary service (20-m. feed), 6-yr. average, was 0.0047¢ per ton (3,140,000 tons raked).

7. BOWL CLASSIFIERS

Bowl classifiers consist essentially of a shallow cylindrical tank in which more or less agitation is maintained by means of rotary rakes or plows; these serve also to move settled sand to a discharge cone or well at the center of the tank bottom. Some means of secondary classification is provided to act on the sand seeking egress through the bottom well; this may be simply rising water (hydro types), or rising water supplemented by mechanical agitation (bowl-rake type); the effect of the latter may be further aided by air-lift circulation.

Hydro-bowl classifiers

These classifiers may be used for separations at as coarse as 35-m., but in general they are used to overflow at 100-m. or finer, making either sand-slime separations or separating slimy water in large quantities from associated granular material.

Hydro classifier (Hardinge Co.), shown in Fig. 14, consists of a shallow tank *a* with obtusely conical bottom (slope about 1 1/2 in. per ft.) and a rim or weir *b*, adjustable in height; spiral rakes *c* carried on center column *d*, which is suspended from an enclosed-gear drive mechanism *e* mounted on a framework *f* which is carried on the bowl; a conical collecting and reclassifying chamber *g* containing tangentially directed water inlets *h* and a conical scraper *i* depending from the center-post; and a sand-discharge outlet *j*, which may be either a valved spigot or, as pictured, unvalved, delivering by simple sedimentation into the cylinder *k*, in which water stands at the level of the bowl overflow, and through which a spiral screw transports settled sand to a discharge lip *l*. Item *B* shows a form of reclassifier in which tube *j* is extended downward, with hydraulic water introduced through pipes *m* near the bottom, so that a teeter column (Art. 12) is formed at and above the junction of *j* and *g*. Item *B* shows an alternative method of sand discharge through a plug valve *n*; this is used when considerable water is permissible in the sands.

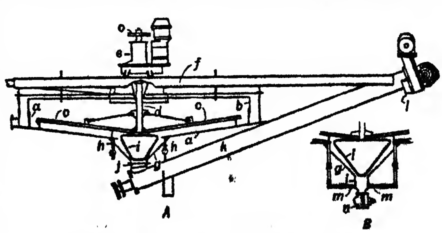

Fig. 14. Hardinge Hydro classifier.

The overflow weir is adjustable vertically through a range of 100% of minimum, which places time-factor under operating control and permits adjustment of mesh of separation

without resort to hydraulic water. This leaves the operator free to use the latter as an additional control on cleanliness of sand. Drive head is fitted with both an automatic lift for relief of overload (Sec. 15, Art. 5) and a manual lift *o* for relief at starting and for setting of rake height. Speed of plows is 1 to 4 r.p.m.

Performance data are given in Table 17.

a *F* = feed, *S* = underflow, *O* = overflow.

Hydroseparator (Dorr. Co.) is essentially a shallow Dorr thickener (Sec. 15, Art. 5) of relatively small diameter, fed at such a rate that solid is forced to overflow. Depth is made sufficient to insure against tramp oversize in the overflow, but this acts to throw much material finer than nominal separating size into the underflow.

Performance. At KIRKLAND LAKE a 16-ft. Hydroseparator was operated in closed circuit with a ball mill grinding siliceous gold ore. Overflow at 8% solids was 250 tons of solid per day. Screen analyses were:

Mesh	200	325	<325
Feed, cumulative %	32.6	40.8	59.2
Underflow, cumulative %	47.5	70.3	29.7
Overflow, cumulative %	1.0	6.0	94.0

Underflow was too wet (58.4% solids) for best grinding efficiency.
The following analyses are for a 50-ft. Hydroseparator making a 100-m. separation on an average ore.

Mesh	35	48	65	100	150	200	<200	% solids
Feed, cumulative %	0.1	1.6	6.5	14.2	21.9	28.0	72.0	6.2
Underflow, cumulative %	0.3	3.6	16.2	37.0	54.9	67.0	33.0	19.2
Overflow, cumulative %	....	....	....	0.2	1.2	3.5	96.5	4.4

See also Sec. 3A, Art. 7.
Density of underflow. Maximum attainable is about 65% solids.

Auto-vortex bowl (Fig. 15) is used, in general, for dewatering and at the same time desliming sands at 48- to 100-m. sizes. It comprises a flat-bottomed bowl *a* superimposed on a Nordberg-Wood type sand cone *b* (Art. 9). Junction between the fixed bowl and the vertically oscillating cone is made by a rubber diaphragm *c*.

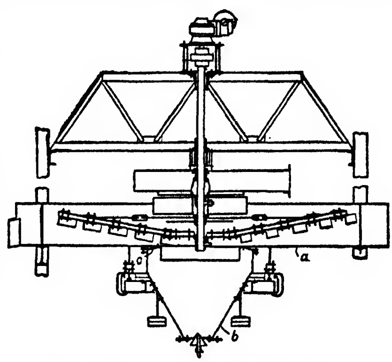

Fig. 15. Auto-vortex bowl classifier.

Noranda aerator classifier. See Sec. 12, Fig. 3.

Design of hydro-bowls. Overflow is normally of sufficiently low pulp density so that the area of the bowl in which current is rising can be designed on the basis of the volume of water to be overflowed, and the free-settling velocity of the largest particle of heavy mineral to be taken over. Depth of bowl over rakes depends upon rake speed and the mesh of separation; for coarse separations the bowl is shallow and rake speed is relatively high in order to get aid from agitation in carrying over the coarser overflow particles; for fine separations the bowl is made relatively deep and rake speed is kept to the minimum that will remove settled sands; in such operation the use of hydraulic water is essential, if a clean separation is desired, since much slime is included in the settled material. As a result, density of underflow is relatively low.

Bowl-rake classifier

Description. The bowl-rake classifier (Fig. 16) consists of a typical rake classifier upon the overflow end of which is superimposed a hydro-bowl *a*, normally about 6 to 8 in. deep at the periphery, with bottom coned on a slope of about 2 in. per ft., the bowl connecting by the central circular well with the pool in the rake compartment at a level below that of the surface of this pool. The rotating rake mechanism *c*, driven independently of the reciprocating rakes, operates in the bowl. In one make ring *d* with air lift *e* comprises a circulating mechanism for return to the bowl of sand that does not settle freely in the rake compartment (CRITICAL-SIZE CONTROL).

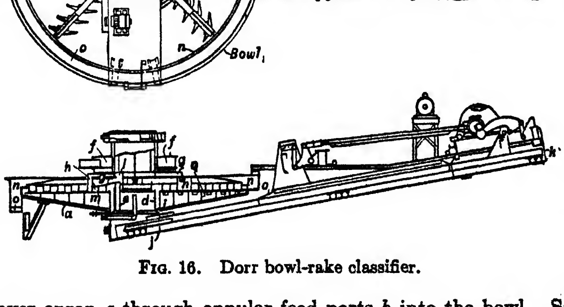

Fig. 16. Dorr bowl-rake classifier.

Feed is introduced into annular box *f*, distributes therein, and flows thence over apron *g* through annular feed ports *h* into the bowl. Sand settles and is raked to the central well, where it falls through annular opening *i*. That part of the settled sand heavy enough to settle to the rakes *j* is raked to the sand-discharge lip *k*; the sand that

does not settle teeters in and below the ring *d*, and the teetering column is bled off at the bottom (coarsest part) by a current generated to and through air lift *e* (CRITICAL-SIZE CONTROL), whence it discharges into splash head *l* and flows through port *m* back into the bowl. Fines overflow the rim of the bowl into an annular launder *o*.

The effect of this combination apparatus is to make it possible to design and operate the settling area and the sand-raking or transport mechanisms separately. This design may be fitted initially to the characteristics of the pulp, and to the tonnage of sand and volume of overflow to be handled; independent adjustment during operation may be made to take care of inevitable day-to-day variations in one or more of these factors.

Sizes. Bowls may be fitted to any of the standard rake classifiers. The procedure in design is to adapt the rake classifier to the sand load and to fit it with a bowl having the proper settling area for the volume of water and size of solid to be taken as overflow.

Performances of bowl-rake classifiers are listed in Table 18.

Use. Bowl-rake classifier is used for separations from 28- to 325-m. (Table 18), but separations at 65-m. or finer predominate; separations at coarser than 35-m. are unusual. The bowl-rake classifier has the great advantage, in the case of feeds that fluctuate in content of desired material, that changes necessary to accommodate changing sand loads can be made without material effect on the adjustments controlling overflow and that by use of variable speed on the bowl rakes, and/or change in dilution, the effect of adjustments in the sand section can be compensated readily.

Dilution varies according to the mesh of the separation. Usual ranges for average ores are about 5 to 7% solids for 325-m., 8 to 12% for 200-m., 13 to 16% for 100-m., 17 to 25% for 65-m., 26 to 33% for 48-m., and 33 to 38% for 28- to 35-m. The range corresponds to difference in settling characteristics of the ores.

If the feed to the classifier is light and slow-settling, higher dilution is required than would be used on a heavy and fast-settling pulp. With some pulps of specific gravity 3.5 to 4.5, the percentage of solids in the overflow is much higher than the above upper limits. Thus in a concentrate-regrind circuit where a 200-m. separation is desired, 15% solids in the overflow is quite common; for a 35-m. separation on a heavy lead-zinc sulphide, it is common to use as high as 45% solids. Both overflow and rake products at high pulp densities tend to be dirty on account of the high viscosity of the pulp. A sharper separation can in all cases be obtained with more dilute pulps, increasing rake and bowl speed to maintain the necessary suspension. It is high dilution with low agitation in any mechanical classifier that makes for the best efficiency.

[a] *F* = feed, *S* = sand, *O* = overflow.

Speed of bowl rakes is usually variable. As between different classifiers, equivalent speeds are lower the larger the bowl. Range for average ores is from 1 to 3 r.p.m. for a 25-ft. bowl to 3 to 9 r.p.m. for a 5-ft. bowl; it may double with heavy-sulphide feeds. In the low range, speed has small effect on density of overflow, but at the higher speeds, the plows aid suspension, increase pulp density, and will cause coarser overflows for a given volume of overflow.

Capacity, expressed in tons solid in overflow per sq. ft. of bowl area increases regularly with size of overflow (which is normally accompanied by an increase in pulp density). Available records show that, for average ores, tonnage of overflow per sq. ft. of bowl area per 24 hr. may be 0.5 to 1 ton for 325-m. separation, 1 to 1.5 tons for 200-m., 2 to 3 tons, for 65- and/or 100-m., 4 to 5 tons for 48-m., and 5 to 7 tons for 35-m. These figures are somewhat higher than those reported in Table 18.

Critical-size control. Air is supplied at 2 to 3 lb. pressure, the volume ranging from 15 to 45 c.f.m.; the volume required to maintain proper circulation is dependent upon the amount of critical-size material in suspension underneath the bowl in the reciprocating rake compartment. Regulation is based on the extent of superelevation of pulp in the reciprocating-rake compartment required to maintain flow into the bowl. SUPERELEVATION normally should not be more than 2 to 4 in. above the level of overflowing pulp in the bowl; air supply is varied to maintain this value.

Comparative tests at LAKE SHORE with and without the critical-size control on a 16-ft. bowl-rake classifier gave the results shown in Table 18*b*.

Table 18*b*. Effect of critical-size control on performance of bowl-rake classifier

Item	Without critical-size control		With critical-size control	
	T.p.h.	% <200-m.	T.p.h.	% <200-m.
Overflow	8.3	91.8	9.1	96.6
Sands	19.0	22.0	30.8	16.2
Total feed	27.3	37.7	39.9	39.3
Circulating load, ratio	2.3		3.4	
Efficiency, 200-m. basis	51.8		69.0	
% <325-m. in sands	13.5		7.4	
% <1,200-m. in overflow	45.0		44.4	

Efficiency ranges from 17.2 to 81.3 at 12 mills reporting, and averages 57%. This average is close to the individual averages for each of the meshes of separation 48, 65, and 100, indicating that within this range efficiency is independent of separating size. Efficiencies for 35-m. separation (2 cases only) are both below average; that for one case at 150-m. is 70.9. Average efficiency of bowl-rake machines is higher than that for rake classifiers, as is to be expected because of the double guard on both sand and overflow products. The difference lies principally in the extent of removal of finished material from the feed (quantity $f - t$ in the efficiency formula), which is 23 average for the bowl *vs.* 14 for the rake; the character of sand product as measured by $c - t$ is only slightly better in the bowl, 50 average *vs.* 48. Circulating loads are correspondingly lower in the bowl (190 *vs.* 250). This is an important factor to consider when the grinding installation is at or near the limit of volumetric capacity (Sec. 5, Art. 12).

NONMECHANICAL DESLIMERS

These apparatus are all horizontal-current classifiers. All comprise a tank with sides converging to an edge or point. Differences lie in the methods of feeding and discharging, and in the shape of the tank.

8. SAND TANKS

Principles. The essential elements are shown in Fig. 17. Pulp enters behind the perforated baffle A and is distributed in a series of streams, as indicated, across the transverse section of the classifier. In order that a particle may settle out of the stream it is necessary that it settle to the bottom before it is carried through the perforated baffle B at the discharge end. On the discharge side of baffle B the velocity of the rising current is $v = Q/xb$ and as x is less than l, all particles that failed to settle before reaching B will be lifted readily. For analysis of the separating action see Art. 6, discussion of Fig. 12, item b, under ***Principle of area.*** It is shown there that the rising velocity for separation at a given mesh c is $V_c = Q/bl$. If the separating mesh is in the Stokes range, the value of V_c in terms of properties of the particle is given in Eq. 7. Hence $Q/bl = gD^2(\delta - \rho)/18\eta$ and

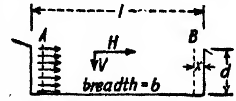

FIG. 17. Whole-current classifier.

$$D_c = \sqrt{18Q\eta/gbl(\delta - \rho)} \tag{11}$$

It will be noted from Eq. 11 that the size of particle in the Stokes range that can be separated in a whole-current classifier is independent of the depth and of the relative proportions between length and breadth. A similar relationship can be developed for the Newton range, and similitude indicates that the same should hold in the intermediate range.

Sloughing-off boxes or **V-boxes** are the simple, crude form of horizontal-current classifier. They consist of a V-shaped box, with sides sloping 50 to 60° from the horizontal, 10 to 50 ft. long, and 4 to 8 ft. deep. They are usually without partitions, but are discharged by means of spigots, gates, or goosenecks at several points along the length. Their principal use is as rough dewaterers and deslimers where clear overflow or clean sand is not essential. The character of separation may be judged from Table 19; differentiation between spigots is slight.

Sand cones

These are the usual form of horizontal-current box. In essence their action is that of zone *D*, Fig. 12, operating above a relatively compact, nonagitated sand bed. In Fig. 18, tank *A* is usually conical but may be pyramidal. Starting empty, and with the hole at the apex closed, when pulp is fed in a distributed stream, as at *F*, the tank fills, overflow of very fine slime begins, and a bed of settled sand builds until it rises to some such position as that shown. If sand discharge is now begun and maintained at a rate equal to that of sand inflow, classification by horizontal-current action takes place radially across zone *D* from central feed cylinder *B* to overflow lip. The settled sand takes no part in the classifying action. That part of the tank below the upper surface of the sand bed is merely a conduit to lead the sand to the bottom outlet. The difficulties in operation cluster around the attempts to maintain sand discharge equal in rate to sand deposition; differences in design are merely different answers to this problem.

Sand discharge. It is impossible to maintain a regular discharge of sand from a sand bed such as is shown in Fig. 18 through an open pipe under the influence of gravity. The first expedient tried in the mills was intermittent manual opening of the spigot, with time allowed between discharges for the coarser material to build up to a considerable depth, and to squeeze out water and suspended slime. This method was succeeded by a mechanically operated intermittent sand gate. The Caldecott diaphragm in a steep-sided cone was the first successful device for continuous discharge of thickened sand. It was followed by the various forms of automatic discharges, gravity-controlled, described below.

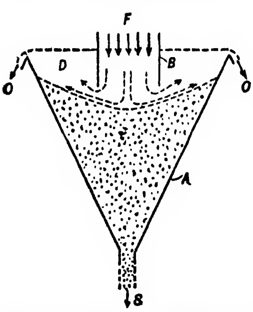

FIG. 18. Elements of sand-cone operation.

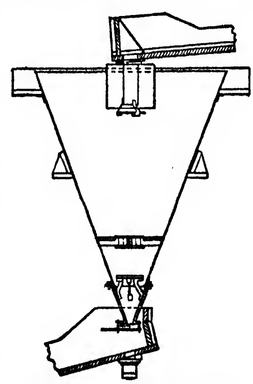

FIG. 19. Caldecott cone.

Caldecott cone (Fig. 19) consists of a sheet-iron conical tank, with apex angle not more than 60° for coarse feed and about 40° for fine, having a disk-diaphragm near the apex, so supported as to leave an annular space between its edge and the cone wall. The cone is center-fed through an inlet pipe 6 to 8 in. in diameter, carrying a disk-shaped baffle a few inches below the lower end. The area of exit between pipe and baffle should exceed the area of the pipe. The feed pipe should project 12 to 18 in. below the overflow level. The lower end of the cone wears most rapidly and is usually a hard-iron casting with removable bushings. It is fitted with an easily replaced sliding gate by means of which the average rate of flow can be regulated. The velocity of the rising current is predetermined within a certain range by means of the cylindrical sheet-iron ring surrounding the feed pipe. This fixes the maximum cross-section of the rising current. In operation the cone is allowed to fill with sand to a height about 2 ft. below the overflow lip at the center and extending nearly or quite to the overflow level at the periphery. The usual dimensions of the cone are 6 ft. (diameter) by 9 ft. (depth) and 8 ft. (diameter) by 10 ft. (depth). The size and placing of the diaphragm are matters of experiment. With sandy feed the diaphragm is placed 12 to 18 in. above the spigot opening and the width of the annular opening is $^3/_4$ to 2 in., the larger figure for finer material. For finest sand and slime the annular opening must be larger, in order to prevent bridging of thickened material. It is made 3 to 6 in. across, and

the diaphragm must, therefore, be carried somewhat higher in the cone. Fig. 19 shows a double diaphragm for treating fine material.

The purposes of the diaphragm are to slow down the flow of sand toward and through the spigot and to prevent center-piping and bridging. Bridging is minimized at the spigot because of the direction from which the solids approach, *i.e.*, obliquely convergent down the walls of the cone from the periphery of the diaphragm. Center-piping is prevented by the intervention of the diaphragm across the axis of the possible pipe. This eliminates rapid settling and discharge of coarse material, which is the cause of piping in ordinary cones. Discharge through the spigot is slowed down by decrease in pressure effected by friction losses in the annular space surrounding the diaphragm, and the rate of approach to the spigot is limited at the same time by the same phenomenon.

Performance. The Caldecott cone has had its greatest development in Rand gold mills, where it has been used to guard tube-mill discharge and to return sands for regrinding. In this service an 8-ft. cone will discharge 400 to 600 tons of <90-m. (0.006-in.) quartzitic sand per 24 hr. in a pulp containing about 30% moisture when the feed contains about 40 to 50% of <90-m. slime.

Results with an 8-ft. double-diaphragm cone at Simmer & Jack are given in Table 20. At a Mexican mill (*10 JCM 287*) a cone 4 ft. 10 in. deep by 4 ft. diam., fitted with a diaphragm 8 in. from the apex, leaving 1.5-in. annular space, was fed at 240 tons per 24 hr. Results are given in Table 21. At the St. Joseph Lead Co., Bonne Terre mill (*57 A 432*), a 6-ft. Caldecott cone handled 400 to 500 tons of <2-mm. sand tailing per 24 hr., made an overflow containing no material coarser than 0.1-mm., while the spigot product averaged 28% moisture. The sand level was held about 2 ft. below the overflow. A sizing test of the spigot product is given in Table 22. Mixed jig and table galena concentrate was discharged from a 6-ft. cone with 11% moisture, but intermittent discharge was necessary on account of the variable feed rate.

Automatic diaphragm cone used at Mt. Lyell (*38 Aa 109*) is shown in Fig. 20. With no sand in the cone, the counterweight closes the spigot valve. When settled sand rises to the cylinder on the plug rod the drag of the sand pulls the cylinder down and opens the valve. Performance is shown in Table 23.

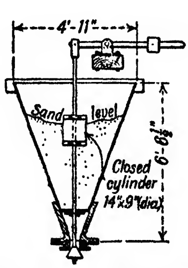

Fig. 20. Automatic diaphragm cone at Mt. Lyell.

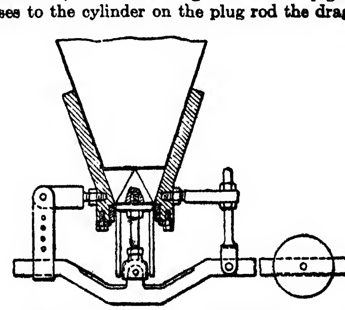

Fig. 21. Automatic diaphragm cone.

Another automatic-discharge device is shown in Fig. 21 (*22 JCM 74*). The counterweight is set to discharge the proper tonnage at the desired percentage of moisture. If the pulp thins down, the velocity of discharge increases, with resultant increase in friction and pressure on the valve plug, then the valve closes somewhat, thus retarding discharge and permitting solids to build up again. The

device gave satisfaction at Ferreira Deep mill on tube-mill cones as compared with manual regulation of standard Caldecott cones. The normal moisture content of spigot product was 25% and a sizing test showed 57% >60-m., 33% >90-m., and 10% <90-m.

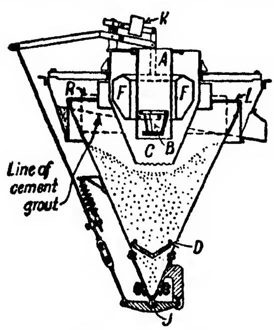

Fig. 22. Allen cone.

Allen cone (Fig. 22) consists of a conical sheet-iron tank, center-fed, with peripheral overflow of slime and automatic regulation of sand discharge. The spigot regulator consists of a spring-controlled link mechanism actuated by a float F. Feed entering the center pipe A is distributed by the baffle B, flows into the tank proper, the sand settles out, and slime overflows the lip L. When the upper surface of the settled sand reaches the position shown in the sketch, water backs up in chamber C, float F is lifted, the valve rod is depressed, and the ball valve J opened. Resistance to opening is varied by the weight K. The valve seat is carried on a swinging plate, so arranged that when the spigot opening is swung to one side for inspection or replacement, the lower end of the cone is closed by a blank plate. New spigot liners can be dropped into place quickly, thus making it unnecessary to shut down. The cross-section of the overflow may be lessened by introducing a reduction ring R, which increases the rising velocity and consequently increases the size of particles overflowed. The effect is shown in Table 24. Diaphragm D serves the usual purpose and additionally acts as a catch-all for a certain amount of tramp oversize, thus minimizing plugging of the valve. Standard sizes are given in Table 25.

Performances are given in Table 26.

Delano (*57 A 440*) says that a 6-ft. cone will treat galena concentrate ranging from 9-mm. down to 5 or 6% <200-m. and carrying 83% water at the rate of 100 tons per 24 hr., will make a spigot discharge containing 12% moisture, and will yield a clear-water overflow. On tailing ranging from 2-mm. to 0.1-mm. the same cone will treat 300 tons per 24 hr., yielding a clear overflow and a spigot product containing 28% moisture. He states that sand coarser than 3-mm. would be difficult to dewater unless it contained a large percentage of fines. Watt (*57 A 440*) says that a 4.5-ft. cone will handle 145 tons per 24 hr. of the undersize of a 10-mm. screen, yielding a spigot product containing 28 to 30% moisture and with less than 3% >200-m. in the overflow solids.

a Desliming cone.

Boylan cone (Fig. 23) consists of a conical or pyramidal tank *a* suspended by rods *b* from a knife-edge on the short end *c* of lever *d*. This lever is suspended at *e*. The long arm connects by means of rod *f* to a short lever *g* whose fulcrum is carried on the lower part of the tank. The working arm of lever *g* carries a conical valve *h*. Feed is introduced at the top at one side, sand settles out and slime overflows on the opposite side. When sufficient sand (about 60 to 75% of the volume of the tank) has collected, the weight of the tank causes rod *f* to be lifted, thus opening the valve *h* and permitting discharge of sand. The tripping point is determined by weights *i*.

Sizing tests of feed and products of a Boylan cone treating rougher-jig tailing are given in Table 27 (*112 J 79*). The efficiency, reckoned on 20-m., is 54.5%.

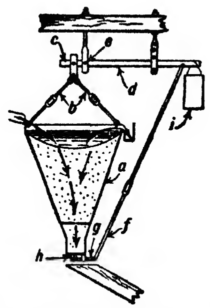

FIG. 23. Boylan automatic cone.

Nordberg-Wood classifier (Fig. 24) is primarily for dewatering sands; it superimposes a vertical sorting column on the characteristic sand cone to act as a safety. It also adds a feed gadget designed to effect spiral flow of the rising current. The essential sand-catching device is the cone *a* mounted in frame *b* which, in turn, is partly supported, via hooks *c* and knife-edges, on the short arm of beam balances *d*. The load is largely balanced, at whatever sand depth in *a* is desired; the remainder of the load is transmitted from the linked ends of *d* through rod *e* to the balance beam *f*, the short arm of which works against the pressure of the settled sand. Thus as the sand level in the cone rises above the predetermined height the long arms of balances *d* rise, *e* is lifted, conical valve *g* opens, and remains open until enough sand has discharged so that the counterweights can depress *e* again. Plug *g* is supported on pin *h* as shown, free to tilt if oversize sticks in the valve; this closes one side of the valve and directs the rush of sand against the obstruction, which may be thereby forced out. Feed bowl *i*, with radial vanes on the wall and alongside ports in the floor as shown, is hung on ball bearings on center-post *j*. Feed launder *k* is arranged for tangential entry of the feed stream, the impulse of which against the vanes revolves the bowl. Sweeps *l* on the underside transmit the swirl to the liquid in the cone. Ring *m*, adjustable in diameter, is provided to permit adjustment of the area and, consequently, velocity of the overflow stream.

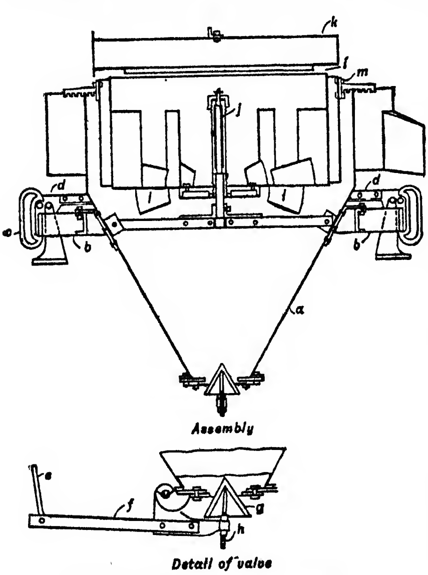

FIG. 24. Nordberg-Wood classifier.

Wuensch (*U. S. Pat. 2,125,663*) describes hydrometer-electric control of a sand cone in closed circuit with a grinding mill. Hydrometers placed just above the sand discharge, at the overflow level, and in the feed well, close and open electrical circuits actuating water-supply valves, ball-mill feeder, and a pump from cone-sand discharge to the ball-mill feed box. A stirring mechanism on a hollow shaft keeps the settled sand relatively fluid and forms a cage around the sand-discharge hydrometer. Operation is obvious.

Action in a sand cone is substantially free settling, with both horizontal and vertical currents. The construction of the feed pipe and its relation to the sand bank are such that the pulp stream starts flowing horizontally in all directions. Heavy, coarse sand is dropped near the center and finer sand near the periphery. With all conditions constant, the surface of the settled solid stabilizes in such a position that the rising velocity in the annular section at the overflow level is just sufficient to lift the coarsest overflow particle, and settled solid is withdrawn through the spigot at a rate just equal to that of deposition.

Sizes and moisture content of the products relative to size and moisture content of the feed are affected by change in rate and character of feed and in size of spigot opening. If the size of particles and tonnage of solid matter in the feed remain constant, change in the amount of water sent to the classifier does not affect either the size of products or the moisture content of the spigot discharge permanently. Increase in quantity of feed water causes instant increase in rising velocity of the overflow pulp with consequent scour of the sands, until the velocity over the increased cross-section is the same as it was before the change, when deposition and spigot discharge again proceed at equal rates. Decrease in quantity of feed water causes deposition and constriction of the overflow stream until deposition and spigot discharge again equalize. Decrease in size of feed particles without change in pulp volume results in lessened deposition and, if discharge continues at the same rate, lowering of the sand surface and increase in cross-section of overflow stream. This results in lessened velocity of the overflow stream and increased deposition until deposition and discharge rates equalize. At this time, since finer material is depositing, finer material also overflows. Coarser feed produces coarser overflow and coarser spigot product.

The moisture content of the spigot discharge is dependent largely upon the percentage of voids in the settled solids, when packed as tightly as they will pack under the conditions of settlement. Coarse material has less voids than fine, hence less moisture; material containing particles of considerable range of sizes has less voids than that closely sized and hence less moisture. Concurrent change of moisture content and tonnage and/or size of feed particles may completely change the character of the discharge through a given spigot. Thus concurrent decrease in moisture content and solid tonnage decreases overflow velocity and tends to cause deposition of finer material. At the same time the surface of the settled solids falls by reason of excess of discharge over deposition, overflow velocity is further reduced and yet finer material deposited. Assuming ultimate equalization of deposition and discharge, stabilization occurs with a large increase in the amount of fines depositing, and there is corresponding increase in the fineness of both spigot and overflow products. The result, as concerns moisture content of the spigot product, cannot be predicted accurately; the greater size range tends toward less moisture and the finer size toward more. If the reduction in moisture content is sufficiently great and there is enough fine solid present to produce a suspension that acts like a liquid of high specific gravity, the carrying power of the overflow may be sufficient to lift coarse material, and if the spigot is changed to prevent lowering of the sand level, the size of the products and the moisture content of the spigot discharge may be maintained unchanged. When the water content of the feed decreases and solid tonnage increases, the respective effects are conflicting; the volume passing may increase or decrease, the carrying power of the current may increase by reason of an increase in specific gravity, and the sand level may either rise or lower, if the spigot size is maintained. The probable result is coarser overflow and an increased tonnage of coarser sand with slight decrease in moisture content. Concurrent decrease in moisture content and size of feed usually results in marked decrease in size of spigot product and overflow, although, owing to increased apparent density of the overflow pulp, it may be possible to keep the overflow size up by decreasing the spigot opening. All other things remaining constant, increase in spigot opening yields finer products and vice versa. Since the spigot opening is ordinarily the only variable in control of the operator he thereby compensates for changes in quality and quantity of feed.

Use of sand cones. The efficiency of sand-slime separation in sand tanks is as good as or better than that obtainable in mechanical classifiers. Thus the two cones at Mine La Motte (Table 26) show efficiencies of 90% at 200-m. and 78% at 150-m. respectively, and the efficiency of the Boylan cone (Table 27) was 54.5% at 20-m. separation. Hence choice between cones and mechanical classifiers should be made on some other basis. Caldecott cones have not been displaced in closed grinding circuits on the Rand, although mechanical machines have been put in new plants as they have been built. Cones have been and are used in a number of the older metallic mills in the United States and Canada; they have wide use in nonmetallic mills. Certainly if a pulp must be elevated in any event, and if separation efficiencies of the order obtainable in mechanical classifiers are acceptable, sand cones should be used unless the tonnage is so large that the multiplicity of tanks necessary makes an unwieldy support and distribution problem. For small mills, if first cost is an item, and if maximum flexibility in the grinding circuit is not essential, the cone is definitely indicated until mechanical classifiers cheaper than are now available come onto the market.

9. SLIME TANKS

Slime tanks are nonmechanical deslimers for making separations at very fine sand sizes. Generically, the different forms are the same, and depend for the separation on utilization of the differences in settling rates of particles of different sizes in water. The specific difference between them lies in the method of presentation to the rising current.

Surface-current tank is shown diagrammatically in Fig. 25. Feed is introduced over the feed sole a. The apparent action is that of a shallow current floating across the surface of the body of pulp in the tank. For such a condition the fundamental equation of velocity equilibrium, $d/V = l/H$, would apply. Since, as has already been established, the separating size D_c is a function of the falling velocity V_c of the particle, it follows that with d very small and l relatively large, V_c and D_c will be very small unless H_c is very large. But H cannot be made large because of the drag of the underlying body of pulp, which dissipates the energy of the cross stream in the production of eddies. These are of the general nature shown in Fig. 25 (*27 A 249*). Hence, qualitatively, it appears that H is limited, and very small particles will be dropped in such an apparatus.

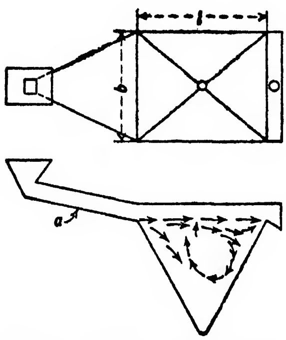

Fig. 25. Surface-current classifier.

Consideration of the condition in a tank such as this which is filling with pulp, focusing attention on the instant before overflow occurs, shows that there is a rising velocity in the tank, of the magnitude $v = Q/lb$. Once overflow has started, unless the feed stream then floats across as a unit, which has been disproved, this same rising velocity persists. Hence the particles dropped out of the surface stream as its velocity diminishes must settle against this rising current, and the velocity of the latter determines the size of the largest particle that can be overflowed. The relationship between size and current is given in Figs. 1 and 2.

Rittinger spitzkasten is the typical form of surface-current classifier. It consists of a series of pointed boxes, similar to the box shown in Fig. 25, increasing in depth and area toward the discharge end. Rittinger recommended that the first box be made about one inch wide for each cubic foot of pulp fed per minute and that the width of each succeeding box be twice that of the preceding. For 20 cu. ft. of pulp per min. he recommended lengths of 6, 9, 12, and 15 ft. respectively for 4 boxes. The sides should slope at least 50° and better 60° from the horizontal. Slopes of the connecting launders should be: about 1/4 in. per ft. for the feed launder, 1/8 in. per ft. from the first to the second box, 1/16 in. per ft. from the second to the third, and 1/32 in. per ft. from the third to the fourth. Richards' experiments (*27 A 249*) indicate that the feed sole should slope about 5° from the horizontal and should enter on the same level as the overflow. The overflow should be level. Eddying will invariably cause much slime to enter the spigot products. Discharge of coarse material is made through pipe-and-plug spigots at the apex of the box; fine material is discharged through goosenecks. In some cases successive boxes are joined so that the upper edge of the division wall is below the overflow level as n Fig. 36 and no connecting launders are needed.

a Baffle plate in second box to direct current downward.

Performance of a 2-box machine treating lead ore, the overflow from a hydraulic classifier, is given in Table 28 (*1 OD 462*).

Desliming cone is a cone with about 60° apex angle, a central feed well, and a distributing septum in the well to eliminate plunge of the feed stream. The action is simple sedimentation against the rising current caused by the overflow. $v = Q/A$, where A is the area, at overflow level, of the annulus surrounding the feed well.

Callow tank (Fig. 26) is an inverted cone with 60° apex angle. The overflow rim is a cylindrical steel band, cleated at intervals to the cone wall near the top, the joint made tight by first packing with oakum and then pouring in a thin cement grout. An endless rubber belt stretched tightly around the metal band is readily leveled, after the tank is full,

by tapping with a wooden mallet. Spigot discharge is effected through a bushing or plug cock at the apex or by a gooseneck siphon. Feed is introduced at the center through a pipe 5 to 12 in. in diameter projecting 6 to 10 in. below the overflow level. A float of 1-in. board, of diameter about 1 in. less than the feed well, perforated with 1/2- or 3/4-in. holes, if desired, is placed in the well. RATING is based on the diameter of the overflow band. WEIGHT ranges from 165 lb. for the 2-ft. size to 650 lb. for the 8-ft.; rated CAPACITY of the 2-ft. cone in desliming service is 24 tons per 24 hr.; 4-ft., 100 tons; 8-ft., 400 tons. In slime dewatering, 4-ft., 6 to 8 tons; 6-ft., 14 to 18 tons; 8-ft., 25 to 30 tons.

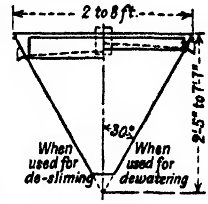

FIG. 26. Callow tank.

Performance. At TONOPAH BELMONT DEVELOPMENT Co. 5-ft. Callow cones handled 70 tons solid per 24 hr. in a pulp containing 85% moisture. The spigot product contained 79% moisture and the overflow 87%. Screen tests of feed and products are given in Table 29. At UNITED EASTERN (*63 A 554*) rake-classifier overflow was sent to 8-ft. Callow cones. The feed to each cone ranged from 160 tons solid and 1,100 tons cyanide solution to 213 tons solid and 970 tons solution (87.3 and 82% moisture respectively) per 24 hr. Spigot discharge was through a 1.5-in. gooseneck fitting 30 in. below the cone overflow. The spigot product at the maximum solid-feed rate given was 73 tons solid and 86 tons solution (54% moisture); overflow, 140 tons solid, 884 tons solution (86.3% moisture). Sizing tests of products are given in Table 30.

Discharge. The rate of discharge of settled material in slime tanks must be such as to prevent build up, or the devices operate as sand tanks, with scour and reduction of area becoming essential parts of the operation (Art. 8).

HYDRAULIC CLASSIFIERS

These are classifying devices characterized by the use of water additional to that of the feed pulp, introduced so that its direction of flow opposes that of the settling particles. The introduced water is called HYDRAULIC WATER. Its quantity, and, consequently, velocity constitute the principal method of control of operation and results.

Hydraulic classifiers are used primarily to sort out and group together particles of different specific gravities. This is the first of the two supplementary steps, sorting and sizing, in certain methods of gravity concentration (Sec. 11). They are occasionally used to sort sized products containing grains of different specific gravities, in which case they constitute the final concentrators. They are sometimes used for sizing nonmetallic feeds comprising particles of substantially the same specific gravities, because they do closer work than is done by the horizontal-current machines, and are, in general, cheaper in such service than screens.

Hydraulic classifiers are of two types, grouping being based on the degree of crowding of particles in the separating zone; if this zone is relatively uncrowded, so that collision between particles is relatively infrequent, and has no appreciable effects on the results of the operation, the machine is free-settling; if the zone is crowded, and collisions are frequent, so that no particle can pass through without material hindrance by the particles maintained therein, the apparatus is hindered-settling. See also Art. 1. There are many forms of each class.

10. FREE-SETTLING HYDRAULIC CLASSIFIERS

General. Classifiers of this type are characterized by the fact that the sorting column is of the same cross-sectional area throughout its length. Many forms have been built and

used. They may be grouped into two classes, *viz.*, launder type and tank type. LAUNDER CLASSIFIER is essentially a launder (Sec. 18, Art. 16) with sorting columns attached to the bottom at convenient intervals. Richards designated the machines in which the upper end of the sorting column comes directly to the bottom of the launder, SHALLOW-POCKET CLASSIFIER; those in which the launder is deepened above the sorting pocket, DEEP-POCKET CLASSIFIERS. TANK CLASSIFIER consists of a relatively deep V-shaped trough or tank with the sorting columns attached to the bottom thereof.

Shallow-pocket free-settling classifiers include many of the early forms of hydraulic machine, such as the Lake Superior hog-trough, Calumet, Tamarack, Yeatman, Ferraris, Evans, etc. (*1 OD 390 et seq.*).

Evans classifier (Fig. 27) is typical. It consists of a launder *A* with bottom inclined about 1 1/2 in. per ft., to which are attached a plurality of pressure boxes *D*, opening by means of adjustable rectangular transverse openings *B*, *C* into the bottom of the launder. Water is introduced into boxes *D* through pipes *F*; a part flows out through spigot openings *G*; the balance rises through the openings *B*, *C* into the launder. Water input is regulated to give maximum rising velocity at the first box and minimum at the last. Feed enters as indicated, with sufficient water (about 75% by weight) for ready transport, and flows along to the first sorting column, where its horizontal rush is decreased by baffle *E*. Some segregation of coarse and heavy solid to the bottom of the horizontal stream occurs in the flow along the launder. The largest and heaviest particles drop through the slots *B*, *C* and pass out through spigot opening *G*, while the solid unable to settle passes on to the second column. The coarsest and heaviest of the remaining particles are here taken out and the process continues until the lightest solids, unable to settle in the relatively slow current of the last sorting column, leave the classifier.

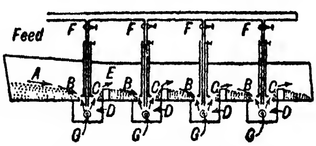

FIG. 27. Evans classifier.

Performance is shown in Table 31. It is reasonably characteristic of the inefficient sand-size separations made by the crude forms of hydraulic classifiers. Comparing the sum of the four spigot products with the overflow, there is a reasonably good size split at about 100-m., much better than can be made by mechanical classifiers or sand cones. As between the individual spigot products there is some differentiation at the coarse end, most apparent in the first spigot, but much of the heavy coarse material in this spigot is unclassified sulphide, which detracts from the value of the material as feed to a final concentrator. As between spigots 2, 3, and 4, the 10%, 50%, and 90% points drop only about one screen interval each, and the average sizes of the fine 10% fractions are only a few hundredths of a millimeter apart.

Efficiency of hydraulic classifiers in concentrating mills is not, of course, to be judged entirely on sizes of the spigot products examined without regard to mineralogical composition. The settling ratios (Art. 1) largely determine the amenability of the products to subsequent concentration. But it is a purpose of the classification to make additionally a separation into short-range grades suitable for efficient final separation on shaking tables (Sec. 11, Art. 22), and performance must be judged also in this respect.

Deep-pocket free-settling classifier is typified by the RICHARDS VORTEX CLASSIFIER (Fig. 28). It differs from the shallow-pocket apparatus by providing pockets above the sorting columns of sufficient size and depth to effect a rough segregation of the feed to the column, sending along immediately most of the material that could not settle in the sorting column proper and holding back material that might settle in the column long enough to give it an opportunity to do so. The vortex fitting used at the

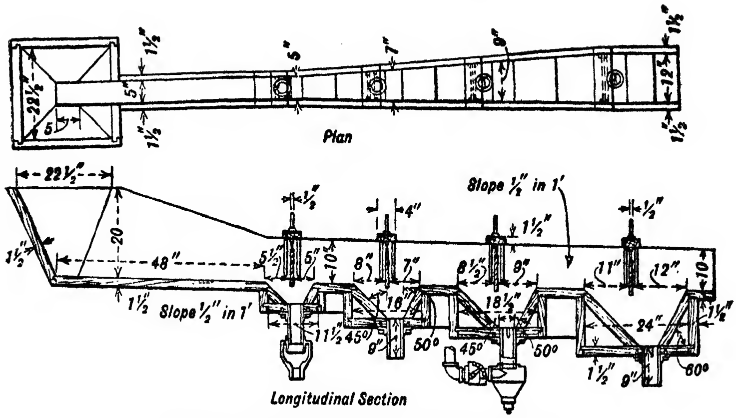

FIG. 28. Richards launder-type vortex classifier.

bottom of the sorting columns is shown in Fig. 29. Water entering the tangential inlet pipe takes on a swirling motion around a vertical axis and retains this motion in rising through the sorting column,

<0.107	15.2	....	....	....	93.4

with the result that eddies around horizontal or inclined axes are eliminated. This elimination goes to prevent the presence of fine sand and slime in the spigot products. The ideal condition in the sorting column is a uniform current vertically upward, but this cannot be attained. A home-made substitute for the vortex fitting is shown in Fig. 30. It is intended to bolt to the bottom of a roughing pocket. Performance of a 3-spigot vortex classifier is shown in Table 32.

Free-settling tank classifier is shown diagrammatically in Fig. 31. Sorting columns are of the same types as used on launder classifiers but the tank affords better opportunity for roughing off slime.

Series classification in cones as practiced at HOMESTAKE (*22 IMM 90*) is shown in Fig. 32. Feed enters the larger cone, which is run with a small discharge bushing so as to overflow about 88% of the total solids. The small cone reworks the spigot product of the first. Sizing-assay tests of products are given in Table 34.

Use of free-settling hydraulic classifiers is past in mills in which close classification is essential. They are inefficient in both sizing and sorting. But when rough work at relatively high capacities is desired, or a machine that can be knocked together by any carpenter and blacksmith is wanted, they answer as well as or better than the more elaborate hindered-settling types.

11. HINDERED-SETTLING HYDRAULIC CLASSIFIERS

Hindered-settling classifiers differ from free-settling in one characteristic only, *viz.*, that the sorting column is constricted at the lower end. This constriction may be obtained in any way. Several forms of hindered-settling sorting columns are shown in Fig. 33. The same general types are found in hindered-settling as in free-settling mill machines, *viz.*, launder and tank.

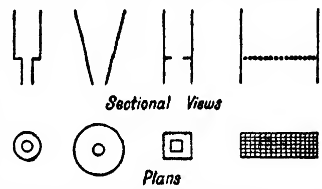

FIG. 33. Methods of obtaining constriction in hindered-settling sorting columns.

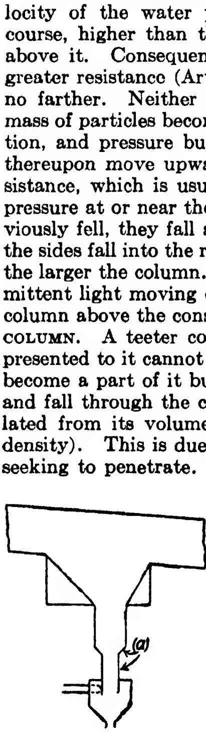
Action in hindered-settling column. The rising velocity of the water passing the constriction is, of course, higher than that in the part of the column above it. Consequently falling particles here meet greater resistance (Art. 1) and some of them can fall no farther. Neither can they rise. As a result, a mass of particles becomes trapped above the constriction, and pressure builds up in the mass. Particles thereupon move upward along the path of least resistance, which is usually the center of the column, until they reach a region of lower pressure at or near the top of the settled mass; here, under conditions in which they previously fell, they fall again. As particles from the bottom rise at the center, those from the sides fall into the resulting void. A general circulation is thus built up, more irregular the larger the column. This continual movement, with the particles at all times in intermittent light moving contact with neighbors, is called TEETER; that part of the classifier column above the constriction in which the teetering condition exists is called the TEETER COLUMN. A teeter column acts as though it were a liquid, in that the lighter particles presented to it cannot penetrate, but appear to float on it; heavier particles penetrate and become a part of it but cannot leave it at the bottom; heaviest particles sink through it and fall through the constriction. Its effective density is higher than the density calculated from its volume and the weights of its solid and liquid constituents (composite density). This is due to the frictional, particle-to-particle resistance offered to particles seeking to penetrate. This resistance is analogous to viscosity. Hence total resistance R' may be expected to be of the general nature of that given by the Stokes equation (Art. 1, Eq. 1), *e.g.*, $R' = K'D\eta'V'$, and the settling velocity of particles therethrough to be $V' = K'D^2(\delta - \rho')/\eta'$, where the letters denote the same items as in the equations of Art. 1, but the primes relate certain of them to the teeter column. None of the primed quantities has been quantified, but qualitative work confirms the equations to the extent that resistance of the teeter column increases as its composite density ρ' increases, and that columns made up of rough and irregular grains offer more resistance η' than one composed of smooth and rounded grains.



a. Reducer and nipple added to change classifier from free-settling to hindered-settling.

FIG. 34. Sketch of one spigot of Richards hindered-settling vortex classifier, launder type.

Launder-type hindered-settling hydraulic classifiers

The simplest of these is a machine obtained by placing a reducer and a short pipe nipple of smaller size on the lower end of the sorting column of a Richards vortex classifier (Fig. 28), and placing the vortex fitting on the lower end of the added nipple. Fig. 34 is a sketch of one spigot of such a classifier. Such a change in an existing classifier will result in a reduction in capacity, but by replacing the sorting column of the existing classifier by a teeter column of larger diameter, and dropping the existing column to a position below the added member, capacity will be maintained. For discussion of the ratio of diameters of sorting column and teeter column, see Art. 12.

Hindered-settling columns. A major difficulty in operation of hindered-settling classifiers is to prevent sand from banking against the walls of the teeter chamber, thus decreasing capacity by decreasing the cross-section of the column. This in itself, if it were a stable condition, could be allowed for in design. Actually, however, it is cyclic, and, since rising velocity increases as column diameter decreases, the product of the column becomes progressively coarser as it sands up, then is suddenly finer after the accumulated load slumps and discharges. Various methods of agitation have been used to combat this condition. Fig. 35 shows two forms of column in which agitation is effected by the hydraulic water. In the Richards form the converging conical sorting chamber is perforated with vertically alternating rows of radial and tangential water inlets which serve to maintain free movement and maximum fluidity in the mass of teetering grains. The Deister column consists of a downwardly converging cylindrical casting *a* in which are suspended a number of cone-shaped castings *b* with radial slots staggered vertically as shown. Water enters radially through a plurality of small holes from the pressure chamber *c*. The columns may be bolted directly to the bottom of a launder, but are better placed at the bottom of roughing pockets. Mechanical agitation is used in the Richards-Janney type (see below).

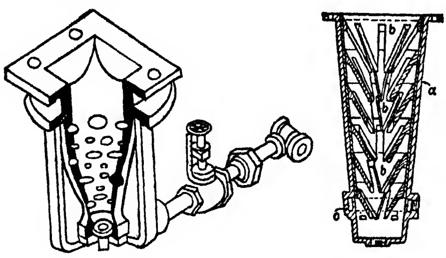


FIG. 35. Hindered-settling sorting columns.

Tank-type hindered-settling classifiers

Richards-Janney classifier (Fig. 36) is of the tank type with hindered-settling sorting columns. It consists of a number of pyramidal settling tanks, increasing in size from feed to discharge end, so joined as to form weirs well submerged. To the bottom of each pyramidal frustum is attached the classifying mechanism proper, consisting of a cylindrical teeter chamber *a*, converging at the bottom to the cylindrical glass-walled sorting column *b*, below which is a tangential hydraulic-water inlet *c*. The rotating stirring arms *d* carried on a hollow spindle *e* depending from the worm gear *f*, which is driven by a worm on shaft *g*, prevent sanding in the teeter column, and minimize eddying. Cams *h* on the upper side of gear *f* operate a lifting arm on the tappet rod *i* which carries on its lower end a rubber ball-valve that seats on a bushing *j*. The valve is thereby opened several times per min., according to the tonnage to be discharged (*e.g.*, 2 to 6 times), and discharges into the retarding chamber *k* which in turn discharges through a pipe-and-plug spigot *l*. The rate of discharge is controlled by the size of the spigot opening and by the air cock *n*. Water inlet to each column is regulated by a dial valve *m*. The stirring arms make about 1.5 r.p.m. The glass sorting column, by permitting observation of the actual sorting operation, makes regulation of the classifier easier than otherwise. The intermittent discharge effected by

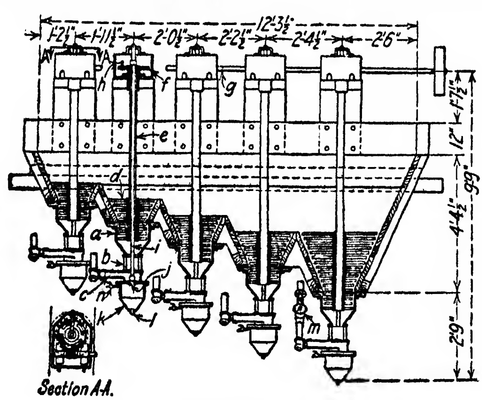

FIG. 36. Richards-Janney classifier.

the ball valve makes it possible to discharge a thick spigot product through a large opening ($^1/_2$-in. to 1 $^1/_2$-in.) and thus decrease water consumption while eliminating clogged spigots. The retarding chamber prevents serious downward rushes of pulp, which would entirely disarrange classification, when the ball-valve opens.

Performance is shown in Table 35.

a 475 tons per 24 hr.

Density-controlled discharge

Modern hindered-settling hydraulic classifiers are designed to eliminate, as far as possible, the necessity for manual control of spigot discharges. This is done by hydrostatic balancing of the quicksands in the teeter columns against some form of automatic control on the discharge ports therefrom. The Bunker Hill, Fahrenwald, and Pellett classifiers are typical.

Fahrenwald sizer (Fig. 37) consists of a tank *A* with divergent vertical side walls, the bottom part of which is divided into classifying pockets *B* by transverse partitions *C*. The

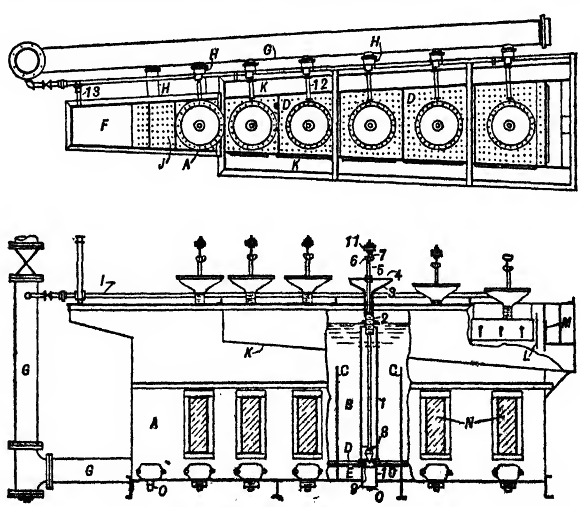

FIG. 37. Fahrenwald sizer.

bottoms of these pockets consist of perforated constriction plates *D*, which separate them from pressure compartments *E*. Hydraulic water from a constant-head tank is supplied

a Length. *b* Numbers refer to Table 32*a*.

through header *G* and individual branches *H* to each pressure compartment. Feed introduced at *F* is agitated by hydraulic water in a preliminary pocket *J*. The suspension flows thence along the upper part of the tank, and the sands settle out, roughly classified, into pockets *B*. Slimes overflow the sides of *A* over adjustable weirs into launders *K*. The finest sands overflow weir *M* after submergence by baffle *L*. Water rising through the constriction plates forms teeter columns with the roughly classified sands which settle in the various classifying pockets *B*. The bottoms of these teeter columns are discharged automatically by a mechanism designed to maintain uniform density of teeter bed. This consists of a standpipe *1*, into which is threaded at its upper end neck *2* of diaphragm chamber *3*, closed at the top by a thin rubber sheet *4*. A small pipe *5* is attached by a watertight clamp to the center of the diaphragm, and, through the medium of wing nut *6* supports valve stem *7*, which is threaded to the wing nut. Stem *7* carries tapered plug *8*, which fits into valve seat *9*. Pipe *1* is slotted at the bottom as indicated to afford connection with *B*. As sands accumulate in pocket *B* water rises in *2* above the outside level, in hydrostatic balance with the teetering suspension in *B*. It thereby exerts upward pressure on *4*, which raises *5*, *6*, and *7*, thus opening valve *8* and allowing sand to escape through spigot *10*. The vertical position of *4* is adjustable by the threaded connection on *2*, and counterweights *11* are provided for fine adjustment of back pressure to control density of the teeter columns. Water admitted through pipe *12* produces downflow in *1* to flush out solids that might disturb the hydrostatic balance. Windows *N* afford observation of the teeter columns to aid in valve adjustment. Spigots *O* (at one side of *10*) discharge the accidental material that passes the constriction plates into chambers *E*. Pipe *13* supplies dilution water.

Motor-controlled discharge involves use of an electric modulating motor to lift the valve stems; the motor is controlled by the action of either a float or a pressure device in standpipe *1*. This arrangement is claimed to make control more sensitive.

Performances at several plants are shown in Table 36.

Bunker Hill classifier (Fig. 38) is similar to the Fahrenwald sizer, differing therefrom in the means of adjusting spigot-discharge rate to teeter-column density. It comprises a plurality of teeter chambers *A* in a rectangular box *B*, successive chambers being separated by submerged weirs *C*. A V-shaped roughing tank *D* surmounts the teeter box; it is fed through a distributing screen at one end and discharges over a weir at the other. Sand discharge is through lift valve *E* and spigot *F*. Valve *E* is opened at predetermined intervals by cam *G* and the intervening link mechanism; the extent of opening at each revolution of the cam is determined by the height of float *H*, which depends upon the composite density of the teeter column

Pellett classifier (Fig. 39) attains automatic spigot discharge by causing the hydrostatic pressure of the teeter column to subtract weight from one arm of a beam balance

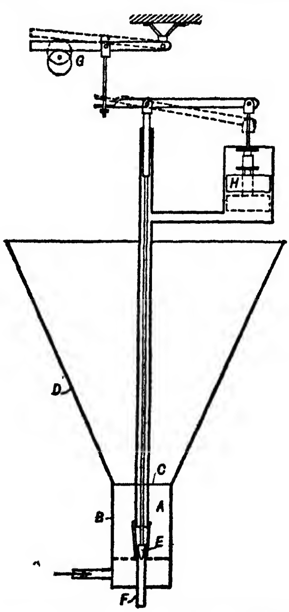

Fig. 38. Diagram of Bunker Hill classifier.

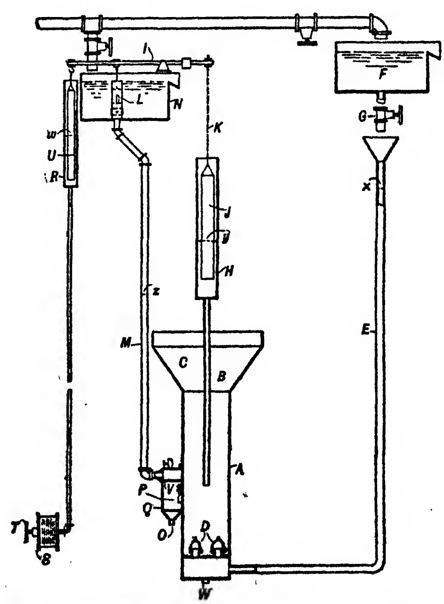

Fig. 39. Diagram of one compartment of Pellett classifier.

which controls a valve, the flow through which controls, in turn, the opening of a flutter valve on the corresponding spigot discharge. In the figure, *A* is an elongated teeter trough compartmented by submerged weirs *B*; *C* is the overlying trough in which roughing is

effected by the horizontal carrying current of the feed stream. Trough A is made exceptionally deep so that the lower part of the teeter column itself will serve to distribute hydraulic water introduced through capped nozzles D. Taking A as typical of any one compartment of a multi-spigot apparatus, continuously receiving roughly classified sands from the transport stream in C, it receives at the same time a constant flow of water through pipe E from constant-head tank F through valve G, manually set to maintain a predetermined level x in E. The corresponding rising velocity in A determines the classification therein, with a feed of given mineralogical composition, and constant teeter-column height and density. Constancy in A is maintained by the hydrostatic balance in column H and the reaction of the water in H on beam balance I. As water level y in H rises owing to increased density of the teeter column in A, float J, suspended on chain K from I, rises and correspondingly depresses slide valve L. Water level z in column M, through which column water flows continuously from constant-level tank N to and out of spigot O, falls, and the outside pressure on flutter valve P are correspondingly reduced; P thereupon opens and sands discharge from A into box Q and thence through O. Column R is a remote-control device; a constant volume of water in R and of air in bellows S maintains water at a level w in R dependent on the extension of S as determined by handwheel T located at the point of remote control; float U is thus caused to load or unload the extended arm of I as desired. Items V are perforated baffles designed to prevent vortex action in Q. W is a drain plug. Glass windows are provided in A and Q and near x as desired. Substitution of items D for the usual constriction plate is claimed to eliminate considerable operating difficulty (J. S. Pellett, *PC*).

Performance. A 20-spigot machine at New Jersey Zinc Co. (Franklin) treats 240 tons per 24 hr. of <20-m. magnetic-separator tailing (Sec. 2, Fig. 106) with a consumption of 3,400 gal. of water per ton of solid. Spigot discharges average 50% solids. Size distribution in products is presented in Table 38.

a Partially deslimed product from an Allen Cone, consisting principally of willemite and calcite with a small amount of minerals of intermediate sp. gr., mainly pyroxene. Each spigot feeds one Wilfley table.

Concenco classifier, also known as St. Joe classifier, is of the constriction-plate type, with a classifying box like the Bunker Hill, but lacking automatic features. Spigot discharge is controlled by changing spigot bushings; water, by pinchcocks on rubber hoses from the header. Uniformity of results depends on constancy of feed characteristics.

Performance. At the Leadwood mill a 10×140-in. 14-spigot machine handles 1,900 tons per 24 hr. with a consumption of 420 gal. of water per ton of solid. Screen tests of feed and products are given in Table 39. At the Federal mill (St. Joe. Lead Co.) a 10×240-in. 24-spigot machine is fed 4,400 t.p.d.; at Mine La Motte a 10×120-in. 12 spigot machine receives 700 t.p.d. Size distribution of products at the latter plant is similar to that at Leadwood (Table 39).

Table 39*a* shows a condensed comparison of the screen analyses of Table 39.

This breakdown indicates that the classifier was making essentially only 6 products of different concentrating characteristics, *viz.*, spigot 1, spigots 2 to 7 incl., spigots 8 to 10 incl., spigots 11 to 13 incl., spigot 14, and the overflow. This is not to say that a 5-spigot machine would have made the same size separation; it would not. Rather, by comparison with a similar analysis of screen test 5 on Table 36*a* (which is the only test on Table 36*a* that is properly comparative), it indicates that the advantage of automatic control of spigot discharges lies in reduction in the number of spigots required to do a given job of separation, and puts the choice on the balance between size of tank and complexity of apparatus. If the tonnage running is so large that the spigot products of the automatic classifier must be split to two or more tables, for example, the longer trough of the nonautomatic machine and its ability to do the splitting nearer the point of subsequent treatment are advantages in its favor.

Delano classifier (Fig. 40) is essentially a slime cone with hydraulic water added so as to produce hindered settling. The teeter column is maintained above and around the adjustable conical plug in the apex of the apparatus.

Performances at three of the Missouri mills of St. Joseph Lead Co. are given in Table 40.

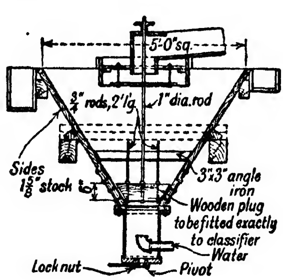

Fig. 40. Delano classifier.

a Final size <200-m. in all products.

12. DESIGN OF HYDRAULIC CLASSIFIERS

There are several cases to consider, *viz.*, (1) free-settling shallow-pocket launder type; (2) deep-pocket types; (3) tank types; (4) hindered-settling columns for any of the above. The first case involves design of the free-settling sorting column and the launder, and consideration of the diameter of the spigot aperture; the second, that of a roughing pocket above the sorting column, whether the latter be free- or hindered-settling; the third, the design of the tank for removing slimes; the fourth, the relative areas of sorting column and teeter chamber.

Design of free-settling sorting column. The data required are: (1) tonnage of solid matter to be passed; (2) average size of all of the light-mineral grains that are to settle; (3) average diameter of the smallest light-mineral grains that are to settle. From Fig. 2, or from the proper formula (see Art. 1), or best, from laboratory settling tests on the material to be classified, determine the velocity of rising current necessary to raise all light-

mineral grains that are to be overflowed; also the average free-settling velocity of the light-mineral grains that are to be settled. The difference between these two figures gives the average settling rate of the light-mineral particles in the spigot product. The volume of the tonnage to be dropped per unit of time, reckoning all solid as having the specific gravity of the light-mineral, divided by the resultant falling velocity of this material, gives the average solid cross-section of the falling stream of solids. The area of the sorting column should be made at least 50% more than this to allow for voids in the mass of settling grains. This allowance, plus the additional allowance that is inherent in the calculation because of the smaller volume and higher settling velocities of the heavy-mineral grains, is sufficient.

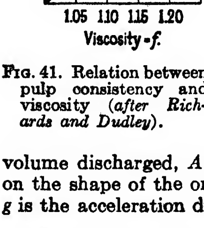

Fig. 41. Relation between pulp consistency and viscosity (*after Richards and Dudley*).

Launder slope and size must be such as to cause the material to travel between sorting columns with the water available. General data on launder slopes are given in Sec. 18. Normally a slope between 1/2 and 1 in. per ft. will be sufficient.

Spigot diameter, effective head on spigot, size of particles to be discharged and moisture content of spigot product are interrelated.

Flow of sandy pulps through pipe-and-plug spigots is different from that of water by reason of friction of the solid particles against the walls, and inner friction of the mass. Richards and Dudley (*51 A 398*) call the sum of these effects the viscosity of the pulp and give the curves shown in Fig. 41 for determination of this factor, f. These curves are the result of experimental work with a siliceous sand (sp. gr. = 2.72) ranging in size from about 0.1- to 1.4-mm. The experimenters used this value in the formula, $Q = Ac\sqrt{2gh}/f$, derived from the fundamental hydraulic-flow equation, where Q = volume discharged, A = area of spigot opening, c is a coefficient of discharge depending on the shape of the orifice, ranging from 0.85 to 0.95 for ordinary pipe-and-plug spigots, g is the acceleration due to gravity and h the head on the orifice.

Example: Required the size of opening to discharge 40 tons of sand (0.1~1.4-mm., sp. gr. = 2.81) per 24 hr., as a pulp containing 25% solids, through a pipe-and-plug spigot with conical receiving end, under a head of 3 ft. The percentage of sand by volume is the governing factor in this case and is 10.6. From Fig. 41, f for this pulp is 1.17. Using c.g.s. units and substituting known quantities in the flow equation

$$A = \frac{1.17 \times 1{,}430}{0.88\sqrt{2 \times 980 \times 91.4}} = 4.5 \text{ sq. cm.}$$

and the diameter of the spigot = 2.4 cm. = 0.94 in. For coarser sands, higher values of f must be used and *vice versa.* With sand of the size and sp. gr. experimented with, the maximum volume percentage that could be continuously discharged without clogging was 13.

The spigot aperture should be as large as is consistent with the head and the volume of material to be passed. The limiting lower diameter is theoretically 3- to 5-times the

diameter of the largest particle passing (see Sec. 18) but this factor rarely enters on account of the fact that tonnage requirements demand a larger opening.

Design of roughing pocket is the same for both free- and hindered-settling classifiers. The fundamental principle is that the rising velocity across the area xy (Fig. 42) should be the same as that in the free-settling column below. The volume moving past this section is that of the incoming pulp plus the added rising water less that of all previously settled solid. It is wise to keep the section x–y as nearly square as possible in order to reduce eddying. The slope of the sides of the pocket should be between 60 and 75° from the horizontal, the steeper the better, in order to prevent sands from banking. If banking occurs the work of the column is disarranged every time the bank caves; this is a frequent occurrence unless the feed is extraordinarily regular. Steepness of slope must be balanced against resulting loss of headroom.

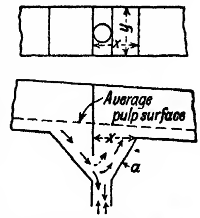

FIG. 42. Roughing pocket.

Design of classifier tank is the same for both free- and hindered-settling machines. The tank is fundamentally a deep pocket for roughing out slimes and is, therefore, calculated to have a surface area such that the velocity of the rising current across the horizontal section at the level of the overflow lip will lift the coarsest particle that it is desired to overflow. The volume of rising current is the feed-pulp volume, plus the total volume of hydraulic water rising in all sorting columns, less the volumes of solid passing out of the spigots. The slope of the sides and discharge end should be at least 60° from the horizontal and better 70 to 75°, to prevent banking. The feed end may slope as little as 45°, dependence being placed on the plunging effect of the incoming pulp to prevent banking here. The bottom slope should be 1 1/2 to 3 in. per ft.; the greater slope gives greater capacity but tends to throw oversize into the later spigots. The sides of the tank necessarily flare toward the overflow end. Their slope is kept constant throughout the length. A safety spigot without rising current should be provided beyond the last hydraulic sorting column in order to discharge sand that is carried past this column but cannot be overflowed. This spigot may discharge continuously or intermittently according to the performance of the classifier; its product will be predominantly fine sand, but will contain considerable slime.

Design of hindered-settling column. The area of the constriction is determined in the same way as the area of a free-settling sorting column. The constriction may be a hole in a plate or at the bottom of a conical tube, if no rising current is to be employed, but with rising current a plurality of small holes is better than a single large one. Experiments at ANACONDA (*46 A 266*) indicated that tubes a couple of inches in length tapped into a plate were better than a perforated plate or screen alone. The ratio of the area of the teeter chamber to the area of the constriction is important. Experiments at ANACONDA (*ibid.*) showed that for each size of grain there is a certain maximum density that can be maintained in the teeter chamber and yet permit discharge of solid through the constriction. If the ratio of the area of the teeter chamber to that of the constriction is too great, no sand can fall through the constriction when full teeter exists, and if the current is reduced to allow sand to fall, banking occurs in the teeter chamber and capacity is reduced; if the ratio is too small, teeter cannot be maintained but free settling will take place. The ANACONDA experiments indicated that the PERMISSIBLE DENSITY, meaning that co-existing at full teeter with free discharge through the constriction, varies inversely as the square root of the surface of a given weight of grains. The ratios of area of teeter chamber to area of constriction necessary to give the permissible density for different grain sizes may be read from Fig. 43.

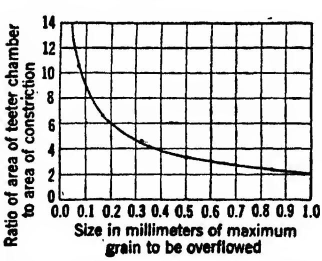

FIG. 43. Ratio of areas of teeter chamber and constriction in a hindered-settling column.

Design of a hindered-settling tank classifier involves all of the elements of design of other types.

Example: To design such a machine with 4 spigots, to treat 200 tons per 24 hr. of <2.5-mm. feed in a pulp containing 25% solids, overflow <0.07-mm. material, and divide the sands into 4 products of such nature that the size range of the light-mineral particles will be the same in each spigot. Assume that screen analysis of the material shows the following size-weight relations: <0.07-mm., 8 tons per 24 hr.; 0.07∼0.68-mm., 72 tons; 0.68∼1.29-mm., 56 tons; 1.29∼1.90-mm., 32 tons; 1.90∼2.5-mm., 32 tons.

To determine the constriction area for the first sorting column: The volume of solid to be passed per second, taking the sp. gr. of the light mineral at 2.6, = 4,040 × 32 = 129,000 cu. mm. The mean diameter of the solids that are to settle = (1.90 + 2.50)/2 = 2.2-mm. The settling velocity of the mean particle = 178 mm. per sec. (From Fig. 2, observed data.) The settling velocity of the smallest particle = rising current to be supplied = 163 mm. per sec. The net falling velocity of the solid = 178 − 163 = 15 mm. per sec. The cross-section of the falling solid, considered as a solid bar, = 129,000/15 = 8,600 sq. mm. The area of the constriction should be 1.5-times this area = 1.5 × 8,600 = 12,900 sq. mm. In similar fashion the areas of the other constricted sections are found to be: column 2, 6,680 sq. mm.; column 3, 14,100 sq. mm.; column 4, 11,030 sq. mm. If single pipes were to be used for the sorting column, 5-, 4-, 6- and 5-in. pipes respectively could be chosen. Most designers would furnish 5-in. pipes for the first two columns and 6-in. for the last two on account of greater simplicity in construction. The areas of teeter columns may be obtained by multiplying the constriction areas by the following factors taken from Fig. 43: No. 1, 1.5 (extrapolated); No. 2, 1.9; No. 3, 2.8; No. 4, 10.5; making the areas, on the basis of 5- and 6-in. sorting columns as above, 30, 38, 81 and 304 sq. in. respectively. The corresponding nearest standard pipe diameters are 6 in., 7 in., 10 in., and 20 in. The length of sorting column necessary increases with the size of material that is to be overflowed. Bardwell (*46 A 266*) states that 4 in. is sufficient for a deslimer column and 8 in. for most cases. The area of the tank at the overflow level is computed to give a rising current of 4.1 mm. per sec. with the feed water plus the rising hydraulic water overflowing. The feed water is 600 tons per 24 hr. The volume of hydraulic water rising cannot be calculated accurately but may be estimated with sufficient precision by assuming that 50% of the area of the constriction is unoccupied by solid. Under this assumption the available area in 5-in. standard pipe is 6,450 sq. mm. and the volume rising, at 163 mm. per sec., is 1,050,000 cu. mm. per sec. The volumes from the other columns are 755,000, 642,000, and 38,200. The total overflow is 8,805,200 cu. mm. per sec. The required area = 8,805,200/4.1 = 2,140,000 sq. mm. = 23.2 sq. ft. A tank averaging about 2 to 2.5 ft. wide by 9 to 12 ft. in length is indicated. The depth of the tank and the size of spigot opening are interdependent. The first spigot must discharge 32 tons of solid per 24 hr. with, say, 96 tons of water. The determination of proper depth (head on discharge) and diameter of spigot is made by trial and error. Assume 4 ft. head. Then, from equation $Q = Av$ the spigot diameter must be 1 3/8 in. If a smaller spigot opening is desired, the tank must be made larger and *vice versa*. The slope of the tank bottom should be at least 1 1/2 in. per ft. and this slope, with the depth above the first spigot fixed, fixes the depth above the other spigots. From this depth the diameters of the other spigots may be computed.

13. CENTRIFUGAL CLASSIFICATION

Centrifugal classifiers are apparatus in which the sedimentation forces acting on particles in the classifying pool are increased far above gravitational magnitude, to the extent of 1,000 times gravity, if desired. This is done by rotating the classifying tank at high speed around an axis perpendicular to the general direction of sedimentation. As a result of the increased forces acting, smaller particles can be settled (*i.e.*, a finer size split made), and size separation can be effected in denser pulps than is possible in anything like comparative times by gravity.

Bird centrifugal classifier (Fig. 44) is the best known of present-day (1943) machines. Essentially it is a spiral classifier (Art. 3) with centrifugal force substituted for gravity.

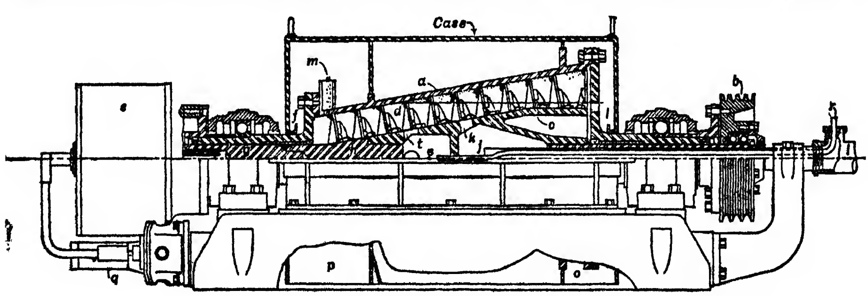

Fig. 44. Bird centrifugal classifier.

The tank comprises the truncated conical shell a which is revolved at the desired speed by drive sheave b. Any section on a through its axis is, then, the equivalent of a section perpendicular to the bottom of the ordinary slant-bottom tank of a mechanical classifier. Member c, carrying a spiral ribbon d, revolves independently of a, in the same direction, but at a somewhat lower speed; it is driven by a planetary-gear mechanism in housing e, which is attached to head f of the bowl, and drives a gear on internal shaft g; this shaft is splined to hollow spiral shaft h. The gear ratios R range from about 15 : 1 to 120 : 1; the differential speed, *i.e.*, the relative rotation S of the spiral is given by the equation $S =$

B/R, where B = r.p.m. of bowl. Feed is introduced through pipe i, which passes through the feed-end trunnion and discharges at j into the interior of the hollow spiral shaft; it passes thence into the bowl through ports k. Fine material in suspension (OVERFLOW) discharges through ports l in the head-end plate (corresponding to the overflow weir of the usual mechanical classifier); these ports are adjustable as to distance of discharge lip from bowl periphery, so that the depth of the pool and, consequently, pool area are variable through considerable limits. The range of adjustment in pool volume is about 4 times minimum volume. Settled material is scraped upslope (toward the small end) by the spiral, and discharges into the housing as indicated, and thence flows out through spout p. Overflow discharges through spout o. Overfeeding is guarded against by a device which transmits pressure from the gear driving the spiral to a torque rod acting against a diaphragm which, in turn, electrically actuates a valve on the feed line, and reduces or cuts off the feed entirely when the pressure (overfeed) exceeds a predetermined limit. The externals of this mechanism are shown at q. Wash water may, if desired, be introduced at r, and flow thence into compartment s and through ports t.

Operation. The same rules hold as hold for slow-speed mechanical classifiers (Art. 6). Agitation increases with the differential speed of the spiral and its pitch (which varies from 2 to 18 in.). The minimum size thrown down depends upon the centrifugal force exerted (which varies as the square of the speed), the area of the pool, the volume of liquid discharging, and the pulp density. It is possible to discharge the sand with very low moisture content (20% on relatively granular ore) on account of the high centrifugal pull on the water against the sloping surface of the bowl "above" the pool level. A variable-speed motor is usually provided, thus making this drying force, as well as the sedimentation pull against the suspending forces, operating variables. Slope of the sides of the bowls varies with the work to be done; usual slope is 10°, range is 7 to 15°.

Table 41. Sizes and relative capacities of Bird centrifugal classifiers

Size, in.	Capacity, t.p.h. of solid	Motor, hp.
18×28	2 to 3	10
24×38	5 to 6	20
36×50	8 to 10	30
36×72	15 to 20	50
54×70	30 to 60	100

Considerable mechanical dispersion of flocculated material is effected by the liquid shear which is brought into play when the feed stream falling from the stationary feed pipe falls onto the inner surface of the hollow spiral shaft, and also when the streams emerging from the ports in this shaft meet the liquid surface of the pool. Insofar as this does away with the necessity for chemical dispersants it constitutes an operating economy, and in cases where purity of products is desirable, it eliminates one source of impurity.

Capacity depends primarily upon specific gravity of solid, separating size and pulp density. Relative capacities of machines of different sizes (large-end diameters by axial length of bowl) are given in Table 41.

Performances. Data furnished by the Bird Machine Co. (*PC*) are given in Table 42.

Table 42. Performances of Bird centrifugal classifiers

Operation	Desliming feed to flotation cells	15-micron classification on thickened feed	100-m. classification on ball-mill slurry
Size, in.	36×50	18×28	54×70
Speed, r.p.m.	800	1,005	400
Centrifugal force, times-gravity	321	240	121
Gear ratio	80 : 1	36 : 1	40 : 1
Differential r.p.m. of spiral	10	27.6	10
Bowl volume, gal.	25	3	105
Beach length, in.	18	12	24
Conveyor pitch, in.	12	5	9
Sp. gr. of solids [a]	4.2	2.5	2.7
Temp. of feed, deg. F.	75	80	110
Feed, g.p.m.	95	45	340
Per cent. solids: Feed	35	51.3	60
Cake	87	69.5	80
Effluent	2.1	24.6	56
Feed solids in cake, %	97.1	80.6	23
Capacity, tons solids per hr.	10.5	8.25	78
Mesh of separation	....	15μ	....

[a] Liquor is water in all three cases.

Use. The centrifugal classifier has passed the experimental stage both mechanically and as a tool or making size separations at sizes below those economically possible with the usual gravity sand-slime separators, or at pulp densities higher than can be treated in gravity classifiers (see Table 42). Its capacity is high in relation to floor space and weight, and power consumption is not excessive. Separation at 1 or 2μ is asserted to be possible in feed pulps containing 20 to 25% solids. It is now being used in cement-blending to separate a high-silica product from the differentially more finely ground lime and shale; it should be useful in separating scuffed fines from attrition-cleaned feeds in nonmetallic flotation, since it will separate at finer sizes than the usual plant deslimers and thus reduce the weight percentage discarded; it would also skim out the small percentage of truly colloidal fines which represent the real trouble makers in the primary slimes in sulphide flotation, etc.

14. DENSITY CONTROL

Since the size of overflow product of mechanical deslimers operating under otherwise relatively constant conditions is determined by the density of the overflow pulp (Art. 6), it follows that maintenance of constant overflow density is a means of maintaining constant size of product.

Methods of density control are either indicating, with change in water supply made by the operator according to the indication, or automatic.

Indicating methods, which are usual, are based on measurements of either the specific gravity, or of the internal pressure of the overflowing pulp.

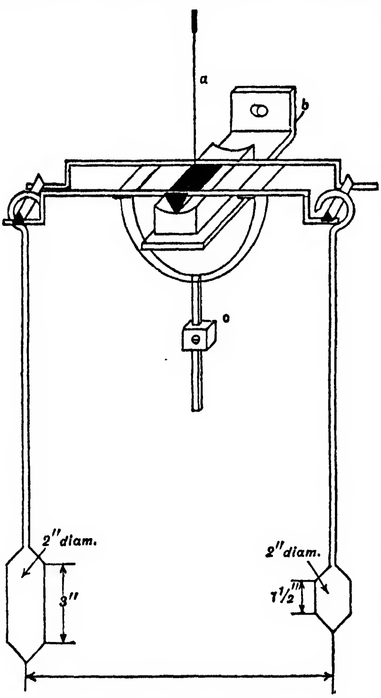

Fig. 45. Morris density indicator.

Specific gravity is usually measured by filling a tared container to overflow and weighing. Density is then read from a chart or table, or, with less likelihood of operator error, a spring balance is used, the scale being graduated to read pulp density directly, tare having been compensated.

Pressure methods ordinarily comprise the use of a HYDROMETER floating in the pool near the overflow lip or, less accurately, of a MANOMETER consisting of of a vertical open-ended glass tube, with the lower end submerged a few inches in the pulp near the overflow weir.

A somewhat more elaborate apparatus (Fig. 45), devised by T. M. Morris at ANACONDA (*PC*), consists of a BEAM BALANCE, with buoys of unequal volume suspended from the arms and submerged in the classifier pool. The difference in upward thrust of the pulp on the arms is equal to the weight of a volume of pulp equal to the difference in volume of the two buoys. Since this volume difference is constant, the difference in thrust is proportional to the pulp density. Pointer *a* reads on a scale calibrated by direct specific-gravity measurements. Fulcrum support *b* is fastened by bolt to a slotted strap which is, in turn, fastened to the wall of the classifier tank in such position that vertical adjustment of the balance is possible. Change of position of sliding weight *c* changes sensitivity. The mechanism is protected from splash by enclosure in a light metal box with holes for the arms and sensitivity leg, and a window for observing the pointer. A shield is placed around the submerged cylinders to prevent sidewise impulse due to swash. At ANACONDA the apparatus is reported to check with the density can within 1 or 2%. Difficulty is to be expected with pulps containing much wood, waste, or dissolved salts that tend to precipitate; frequent inspection and cleaning of submerged parts would then become necessary.

Adams automatic density controller comprises a device for utilizing differences in pressure within the pulp, induced by varying solid percentages, to actuate a motor-controlled feed-water valve. The essential elements of the apparatus are shown in Fig. 46. Pipes *l* and *s*, of unequal length, open at both ends, are mounted on the bottom of box *a*, which is divided into two chambers by the wall *b*. The assembly is fastened to the structure of the classifier in such position that the pipes extend into the pulp as indicated, with h_s about 1/2 in. Air under pressure sufficient to more than overcome head h_l is introduced continuously through pipe *c* and flows into pipes *l* and *s* through orifices *d* and *e* respectively, one being of fixed and the other of variable area as indicated, so that differential orifice resistance may be utilized to regulate the respective pressure drops. By adjustment of orifice *d* by means of handle *f*, pressures in the two down-pipes are adjusted until rise of bubbles from both pipes indicates that the pulp levels in the pipes have been pushed down to their bottom ends. Pipes *g* lead to chambers fitted with flexible diaphragms bearing against the arms of a beam balance, one arm of which is counter-

weighted so that the beam pointer may be brought to center when the pulp columns are at the bottoms of the down-pipes at the pulp density that it is desired to maintain. The supply of air on line c is regulated so that a small flow of excess air is maintained through petcock h when this is partially open; this permits some regulation at the bell of the amount of bubbling.

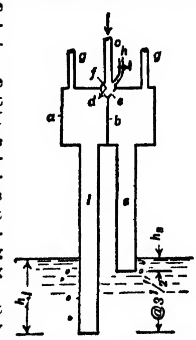

Fig. 46. Adams density controller.

The hydrostatic balance is given by the equation $h_l = h_s\rho + 3\ 1/2\rho$, where ρ = density of pulp. The pressure difference, $\rho(h_l - h_s) = 3\ 1/2\rho$, is not changed by changing the submergence, since this simply adds a constant K to both h_l and h_s. Thus $(h_l + K)\rho = (h_s + K)\rho + 3\ 1/2\rho$, or $\rho(h_l + K - h_s - K) = 3\ 1/2\rho = \rho(h_l - h_s)$. But the pressure difference is, of course, affected by change in the value of ρ. Any such change is immediately transmitted through pipes g to the diaphragm balance, and the scale pointer swings as an indication. At the same time a separate arm swings to close the circuit on a reversing motor actuating a feed-water valve, the direction of swing determining the direction of rotation. This motor circuit is equipped with a timing mechanism which breaks the valve-motor circuit independently, thus insuring slow change in water supply, and minimizing swinging.

Performance. The manufacturers (Mine & Smelter Supply Co.) assert that at an African copper mill one of the units, when checked by specific gravity samples, showed 114 out of 142 samples within 1% of the set overflow density and 26 within 2%. They cite also another operation in which, with a set density of 30% solids, half-hourly samples throughout a shift showed 11 out of 16 samples at 30%, 4 at ± 1%, and 1 at +2%, with a new-feed tonnage range on the closed circuit of 518 to 710 t.p.d.

SECTION 9

AIR SIZING AND DUST COLLECTION

BY

HARLOWE HARDINGE

AND

T. A. FRANKISH, HARDINGE Co.

1. PRINCIPLES

Air sizing and dust collection deal with different facets of the relative motions between the components of mixtures of solids and gases just as water classification, dewatering, thickening, and filtration deal with similar relative motions between solids and liquids. The same fundamental laws apply in both cases; such differences in phenomena as exist flow from differences in density and viscosity of the fluid media.

Definitions. DUST COLLECTION, as used herein, describes generally an operation in which all or substantially all of the solid admixed with a body of gas is separated from it. AIR SIZING is an operation in which separation is effected between particles of different sizes suspended in a gas stream. This separation is made by causing the larger particles to leave the stream in some particular region, whereas the smaller particles travel on. DUST is very fine solid, so slow-settling in a gas that it remains suspended when the movement of the gas as a whole is very small.

Laws of particle movements in gases

The differential movements of solid particles with respect to each other and to the gas with which they are admixed depend upon a number of factors, *viz.*, (*a*) the size, size distribution, shape, specific gravity, moisture content, and degree of dispersion of the particles; (*b*) the velocity, direction of flow, pressure, density, viscosity, temperature, and humidity of the gas; and (*c*) the shape, size, and surface character of the container.

Martin's analogy. Martin (*26 CerS 21*) points out an interesting but not practically useful analogy between liquids and mixtures of fine solids and gases. Such mixtures flow through pipes with little or no segregation; the surface ripples when the mass is suitably agitated; passage of a gas stream through a mass of homogeneous powder produces an effect analogous to distillation, in that a gas rising through the mass at constant velocity carries powder away from the surface at a constant rate (analogous to evaporation), a given volume of gas leaving per unit of surface area per unit of time carries always the same weight of solid (*i.e.*, is saturated), the weight carried increases with the velocity of the stream (analogous to the temperature effect at constant pressure), and beyond a given critical velocity the mass rises as a whole (boiling point).

Settling velocities of solids settling without interparticle collisions (FREE-SETTLING) in gases are approximated throughout the range of particle size and gas velocities by the ALLEN EQUATION (*1 Phil. Mag. 323*).

$$R = Ka^n pu^{2-n} V^n \tag{1}$$

where R = resistance of the fluid to motion of the solid; K is a constant having, however, different values for particles of different shapes and for different relative velocities of

particle and fluid; a = radius of a spherical particle, n has a value dependent upon the value of V, p is the density of the gas; u is its kinematic viscosity = b/p where b = absolute viscosity; and V = relative velocity of particle and gas.

When V is very small, streamline motion occurs, $n = 1$, and Eq. 1 takes the form proposed by STOKES (Sec. 8, Art. 1), *viz.*

$$R = KabV \tag{2}$$

When V is great, the gas becomes turbulent in the region of the particle, $n = 2$, and Eq. 1 takes the form given by NEWTON (Sec. 8, Art. 1)

$$R = Ka^2pV^2 \tag{3}$$

Graphs of these relationships on the same co-ordinates cross, and neither equation holds near the point of intersection. Many equations have been proposed for the intermediate region. That given by Allen is obtained by setting $n = {}^3/_2$, whence,

$$R = Ku^{1/2}a^{3/2}pV^{3/2} \tag{4}$$

A particle falling from rest in a body of gas at rest rapidly reaches a constant velocity (TERMINAL VELOCITY), at which, of course, the gravitational pull is just equal to the resistance offered by the gas. From this relationship (G = weight of particle = gravitational pull thereon = R), since

$$G = v(S - p)g \tag{5}$$

where v = volume of particle, S = its specific gravity, and g is the gravitational constant, it follows, by substitution, that

$$V_T = K[(S - p)a/p]^{1/2} \tag{6}$$

$$V_S = K(S - p)a^2/up \tag{7}$$

$$V_I = K(S - p)^{2/3}a/u^{1/3}p^{1/3} \tag{8}$$

where V_T, V_S, and V_I are terminal velocities for turbulent, streamlined, and transition conditions respectively.

Approximate settling equations. Since the quantities $-p^xa^y$ obtained by multiplying out Eqs. 6, 7, and 8 are very small compared to S^xa^y, the equations are ordinarily written as in Fig. 6, where values of K for air at 70° F. and atmospheric pressure are given.

Values of K must be determined experimentally for the irregular fragments produced in comminution of solids. Martin (*loc. cit.*) obtained experimental values for crushed quartz

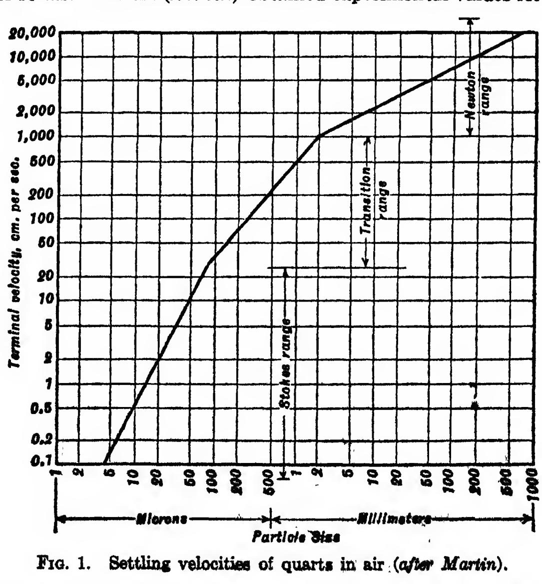

FIG. 1. Settling velocities of quartz in air (*after Martin*).

approximating the graph in Fig. 1, which substantially satisfy Eqs. 6, 7, and 8 in the following forms:

$$V_T = 71\sqrt{a(S - p)/p} \tag{9}$$

$$V_S = 143a^2(S - p)/b \tag{10}$$

$$V_I = 200\bar{a}\left(\frac{S - p}{p}\right)\left(\frac{a}{u} - 10.5\right) \tag{11}$$

in which

$$\bar{a} = \sqrt[3]{\frac{9b^2}{2gp(S - p)}} \tag{12}$$

and is the radius of the largest spherical particle that obeys Stokes' law. For crushed quartz the value $\bar{a}$ may be taken as 50 μ.

Lower limit of Stokes' law is reached when particles approach a size near that of the mean free path of gas molecules, and therefore are subject to less than the normal number of collisions. Gibbs (*Clouds and Smokes, Blakiston, Phila., 1924*) states that for particles smaller than 0.1-μ the CUNNINGHAM CORRECTION should be applied and

$$V_C = V_S(1 + K'\lambda/a) \tag{13}$$

where V_C is the corrected velocity, K' = 0.86, and λ = length of mean free path of gas molecules.

Settling velocities of particles in still air are shown in Table 1.

Table 1. Settling velocities in still air

Size of particle, μ	Rate of fall, f.p.m.		
	Spheres, sp. gr. = 1.0, temp. 70° F. *a*	Irregular grains, sp. gr. = 2.5 *b*	Spheres sp. gr. = 3.0

c Inches per hour.

Gas velocities for solid transport with low concentrations of solid were determined by Dallavalle (*4 #9 HPAC 9/32*). His results for horizontal and vertical ducts respectively are given in Fig. 2. The data substantially satisfy Eqs. 14 and 15.

$$V_H = 6{,}000SD^{0.398}/(S + 1) \tag{14}$$

$$V_V = 13{,}300SD^{0.570}/(S + 1) \tag{15}$$

where V_H and V_V are velocities in f.p.m. in horizontal and vertical ducts respectively and D is particle diameter in inches. Fly ash, 1- to 10-μ, had a marked tendency to cling to the bottom of the horizontal duct and build up, whereupon velocities much higher than the minima were required to keep the duct clean.

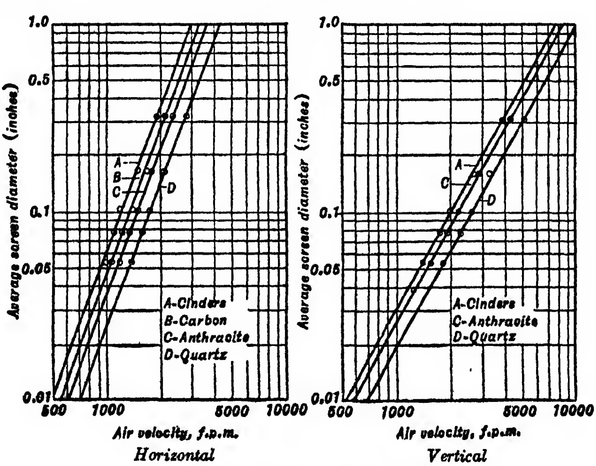

FIG. 2. Air velocities for solid transport.

Energy loss in pneumatic conveying. Dallavalle (*4 #11 HV*) states this to be similar to the loss in hydraulic conveying, if the concentration of material conveyed is not very

great, say 100 gr. per cu. ft. At higher concentrations, the resistance to flow increases owing to constriction and to roughness of particle surfaces. A fair estimate of the drop is possible by assuming the density of the fluid to be that of the air plus the material suspended. In elbows and transitions where the nature of the particle flow cannot be determined, it is best to allow for resistances twice as great as those for air alone.

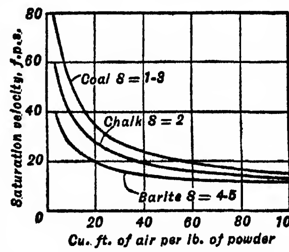

FIG. 3. Velocity *vs.* solid load in horizontal ducts.

Velocity for mixing. Davis (*140 E 1*) gives Eq. 16 defining the gas velocity V_0 (f.p.s.) at which a powder of a given specific gravity and diameter (in.) starts mixing with the stream in a horizontal pipe.

$$V_0 = 54\sqrt{DS} \tag{16}$$

Fig. 3 defines the relation between velocity (V_M) of gas stream and the volume of gas per lb. of different powders (0.005-in. diam. spheres) in an equilibrium (saturation) mixture flowing in a horizontal duct. Davis warns that in design a factor of safety to insure against sedimentation should be applied to V_M values from the chart, owing to nonuniformity of velocity and to dispersion occurring at points of change of direction of flow (centrifugal separation) and to variation in particle size, shape, and feed rate. He suggests a multiplier of at least 1.5 applied to the chart value.

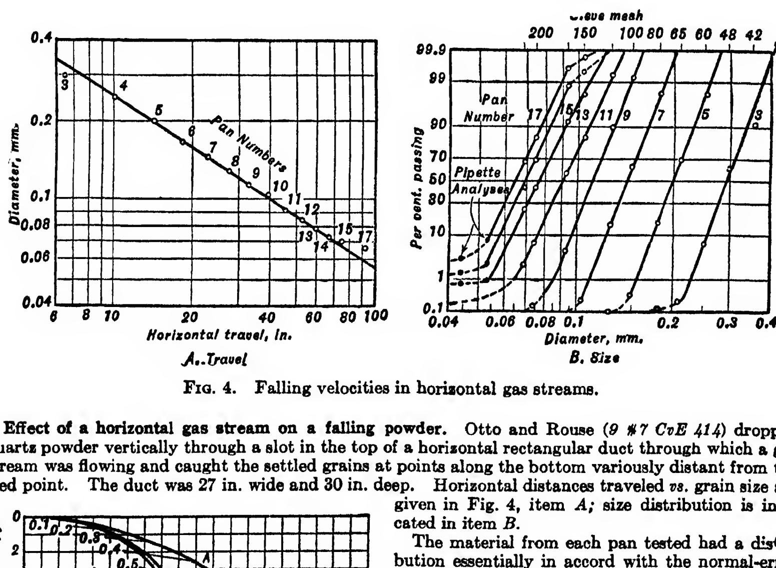

FIG. 4. Falling velocities in horizontal gas streams.

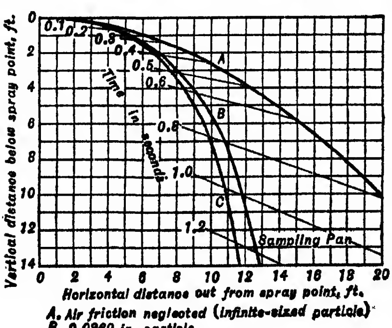
Effect of a horizontal gas stream on a falling powder. Otto and Rouse (*9 #7 CvE 414*) dropped quartz powder vertically through a slot in the top of a horizontal rectangular duct through which a gas stream was flowing and caught the settled grains at points along the bottom variously distant from the feed point. The duct was 27 in. wide and 30 in. deep. Horizontal distances traveled *vs.* grain size are given in Fig. 4, item *A;* size distribution is indicated in item *B.*

The material from each pan tested had a distribution essentially in accord with the normal-error law (straight line on a log plot), except for a small percentage of dust; hence the median and the geometric mean diameters for each size coincide at the 50% line. A vertical line on item *B* would represent perfect sorting; hence the deviation of each curve from the vertical is a measure of the size dispersion about the geometric mean. Otto attributes the decrease in slopes with increasing distance from the point of feed to increase in turbulence along the tunnel of the smaller particles, and to the more angular shape. The straight line of item *A*, the ordinates of which are the 50% points of the curves of item *B*, is evidence of the smooth progression in size secured by this method of classification.



A. Air friction neglected (infinite-sized particle)
B. 0.0360-in. particle
C. 0.0328-in. (20-m.) particle

FIG. 5. Trajectories of powders in still air.

Trajectory of powders in still air was investigated by Lapple and Shepherd (*32 IEC 605*). The solid particles having a density of 115 lb. per cu. ft. were projected (sprayed) horizontally at 25 f.p.s. initial velocity into an air-filled chamber (ρ = 0.067 lb. per cu. ft.). A sample was caught in a 15-in. pan at the location indicated in Fig. 5. Screen analysis

was 0% >14-m., 70% 14~20-m., 30% 20~28-m., 0% <28-m. This is reasonably close to the expectation from the theoretical trajectories plotted.

DUST COLLECTION

2. PRINCIPLES

Dust collection is removal of dust from gas. The usual purposes are one or more of the following: (*a*) To improve working conditions, (*b*) to prevent travel of dust to surrounding territories, (*c*) to prevent dust from re-entering the working atmosphere of a machine or process, (*d*) to permit recirculation of clean gas, (*e*) to save valuable material, (*f*) to decrease building maintenance and wear of plant equipment. The extent of collection necessary depends largely upon local conditions and the nature of the dust. Many types of collectors are in common use, each with different limitations and a characteristic efficiency range. Among the factors influencing selection of equipment and determining its adaptability to a given problem are: (*a*) The properties and characteristics of the dust, (*b*) the quantity to be collected per unit of time, (*c*) the temperature of the conveying gas and of the dust itself, (*d*) the moisture content, (*e*) location of the collector, (*f*) continuity of the operation. The measure of efficiency of a collector is the dust content of the discharged gas rather than the amount of material collected.

Size of dusts encountered in the industrial field varies widely. Most collecting problems deal with sizes in the range from 50-μ to 1-μ. The weight percentage of dusts in the colloidal range is small. Table 2 gives sizes of dusts met with in ordinary milling operations. Fig. 6 gives a basis for relating these to other fine gas suspensions.

Table 2. Approximate median sizes of air-borne dusts

Kind of dust	Median size, μ
Atmospheric dust	0.5
Sand blasting	1.4
Granite cutting	1.4
Trap-rock milling:	
Crusher house	1.4
Screen house	1.3
Disk crusher	0.9
Foundry parting compound	1.4
General foundry air	1.2
Talc milling	1.5
Slate milling	1.7
Marble cutting	1.5
Soapstone	2.4
Aluminum dust	2.2
Bronze dust	1.5
Anthracite mining:	
Breaker air	1.0
Mine air	0.9
Coal drilling	1.0
Coal loading	0.8
Rock drilling	1.0

Types of dust-collectors. Commercial dust-collecting equipment comprises five distinct types, classification being based on the physical principle involved in separation. (*1*) Gravitational collectors, typified by settling chambers; (*2*) inertial separators, of which baffle chambers and centrifugal separators are representative; (*3*) filters, the bag collector being the best known; (*4*) spray-type, represented by scrubbing towers; (*5*) electrical, of which the Cottrell precipitator is the form most used. The sizes of dusts to which the various types are usually applied are given in Table 3.

Table 3. Approximate minimum particle sizes settled in commercial dust collectors

Separator type	Minimum particle size, microns
Gravity	200
Inertial deflectors	50 to 150
Centrifugal:	
Large cyclone	30 to 60
Small cyclone	5 to 30
Mechanical	5 to 30
Washers and scrubbers	0.01 to 30
Filter	0.1 to 0.5
Electrical	0.001 to 1.0

3. GRAVITATIONAL SEPARATION

The simplest and most economical means of removing dust from gas is to reduce the velocity of the carrying stream, whereupon relatively coarse particles can be dropped out in a chamber of reasonable volume. Baffles and deflector plates are sometimes used to aid separation. The principal use of the settling chamber is to rough out the coarser particles and thus reduce dust load in subsequent more effective equipment.

Design of a settling chamber. The average settling rate of the material to be collected should be determined by experiment. An alternative would be to size the dust by screen or other suitable method and calculate settling rate by Stokes' equation, in the form and

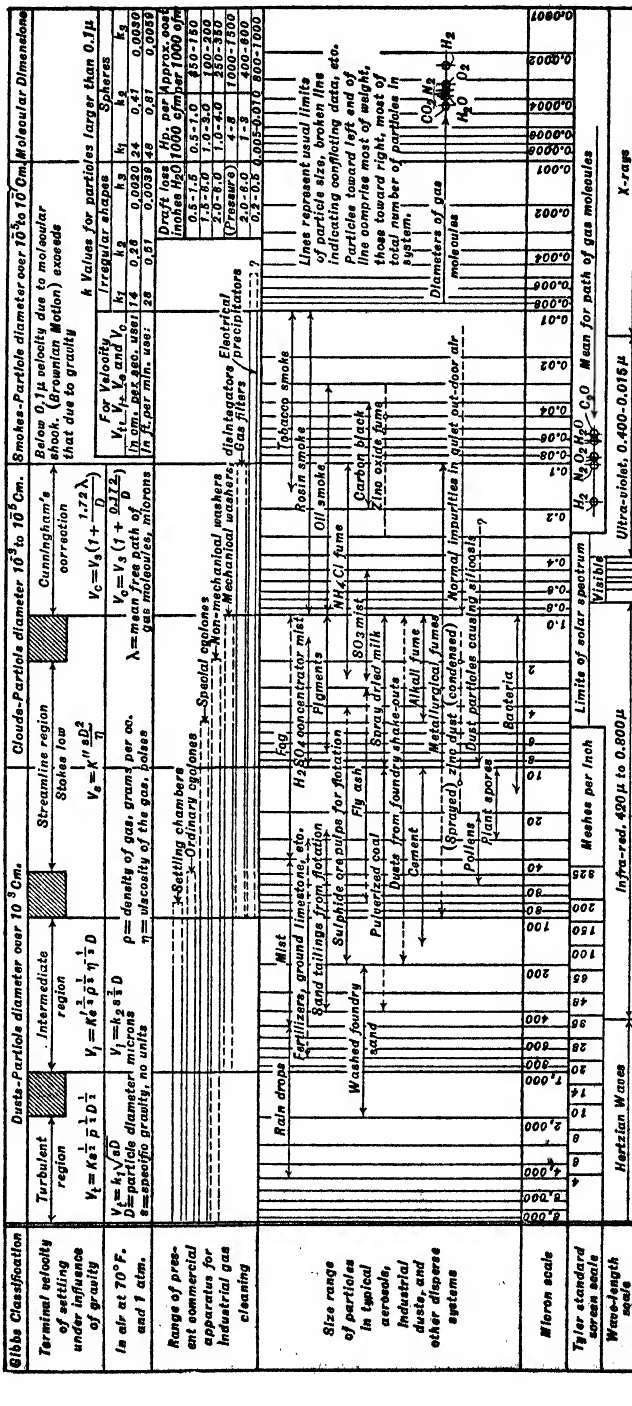


FIG. 6. Data on gaseous suspensions.

with the constants of Fig. 6. A safety factor (EDDY FACTOR) of 0.5 should be applied to a settling rate determined by either method to allow for turbulence at an air velocity of 60 f.p.m.

A common form of chamber (Fig. 7, item *a*) consists simply of an enlargement in the gas duct, sufficient to lower the velocity to the desired extent, usually with one or more baffles, to add inertial effect (Art. 4), and a hoppered bottom for drawoff.

Air velocity through a gravity chamber should be in the range of 4 to 120 f.p.m. for best separation, but cost and available space seldom permit air speeds less than 300 f.p.m. and even this value may be impracticable because of chamber size. Necessary retention period $t_R = h/V_S$ where V_S = terminal velocity of the smallest particle to be removed. Similarly $t_R = hwl/Q$ where w = width and l = length of settling chamber, whence $wl = Q/V_S$. Horizontal velocity of the air through the chamber, $V_H = Q/hw$; whence $h/l = V_S/V_H$.

Pressure drop through the collector depends upon the transitions at entry and outlet. If the collector is a simple rectangular box, the loss may be as much as 1.5 times the velocity head in the inlet pipe; if the pipe leads to the box with a diverging connection, and a conical outlet is used, loss may be reduced to 0.75 times inlet velocity head.

The ratio h/w selected is determined by space limitations, entry design, and the decision on the importance of maintaining uniform flow across transverse area of the chamber.

Example. Assume the specific gravity of the solid = 3.0 and particles down to 74-μ are to be removed. The quantity of air is 1,200 c.f.m. TRIAL 1. Try V_H = 60 f.p.m. V_S for 74-μ particles is 96 f.p.m. (Table 1.) Then $h/l = 0.5V_S/V_H$ (allowing an eddy factor of 0.5) = 0.5(96/60) = 0.82. Transverse area A_T = 12,000/60 = 200 sq. ft. h/w = 1/2 is a good proportion. Then h = 10 ft.; w = 20 ft.; l = 60 ft.

4. INERTIAL SEPARATION

Baffle-type collector. Essentially this is a settling chamber (Fig. 7), fitted with baffles or deflectors, or otherwise so conformed that it effects velocity reduction and a centrifugal action caused by change in air direction, which serves to throw dust into isolated or dead-air pockets. The collector is available with baffles or deflectors of various design or shape, so arranged and spaced as to form a tortuous passage through the unit. It is principally applicable to the removal of the coarser particles in high-temperature installations, since the design lends itself to all-metal construction. It is frequently provided with an auxiliary water-spray compartment to improve the over-all separating efficiency.

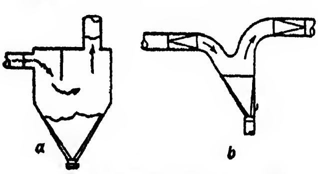

FIG. 7. Baffle-type dust traps.

Venturi dust trap (Fig. 8) consists of a series of Venturi-shaped passages *a* through which the dust-laden gas passes horizontally. The walls of the passages are formed by diamond-shaped ducts *b* which extend from the bottom of the main duct or casing *c* to within a short distance of the top. At the top of each vertical duct or trap *b* there is a small opening *d* into a by-pass area *e* at the top of the main duct. The velocity of the gas increases as it approaches the throat of the Venturi passages, and the momentum of the dust particles causes them to concentrate along the conveying walls. The concentrate passes through narrow slots *f* in the vertical walls of traps *b* and most of the solid drops into the hopper *g*, while the gas passes out at the top through the slots *d*. The traps are arranged in a series of 6, 9, or 12 rows. Dampers *h* control by-pass. The Venturi principle is said to aid in keeping down the resistance; hence the arrangement is suitable for installations having limited draft facilities.

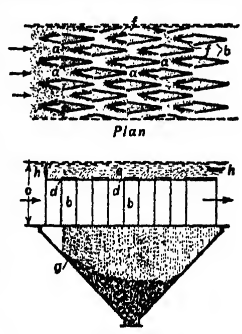

FIG. 8. Venturi dust trap.

Centrifugal collectors

The centrifugal, or CYCLONE, collector is widely used. It accomplishes dust removal through combined velocity reduction and the action of centrifugal forces and is effective principally on coarser particles. Many designs are available with widely different external dimensions and proportions, and internal devices. Modern designs of high-speed and multiple cyclones increase the extent of separation by developing high centrifugal forces and high resistance or pressure drop.

Cyclone design is based on the principle of the vortex. Dust-laden gas enters tangentially near the top and is forced down in an ever-decreasing spiral to the dust-outlet trap. Dust particles are precipitated at the periphery, the separating effect increasing as the apex of the cone is approached. Clean gas forms a vortex in the center and travels upward into the cleaned-air outlet. The dust swirls down into the apex of the cone, or in some cases into a small collection chamber, and is released at the bottom. The outlet for material must be sealed by rotary valves or air locks.[8] Air flow is shown diagrammatically in Fig. 9.

Cyclones are classified as of high and of low efficiency. The former are tubes ranging from 24- to 4-in. diameter. Low-efficiency cyclones seldom show higher than 70% collection from dust <100-m.; they have proved satisfactory for larger particle sizes. They are sometimes used in series, but over-all efficiency, power consumption, and initial cost usually do not justify such a design as compared with a single-pass collector.

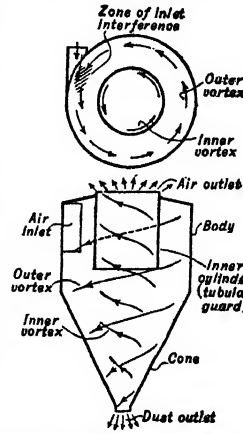

Fig. 9. Diagram of air flow in a cyclone collector.

Advantages of low-efficiency cyclones are that (*a*) standard designs are not covered by patents; (*b*) they are cheap to construct; (*c*) wear from abrasion is usually low because of the low velocity, and light-gage metals can be employed in the construction, (*d*) pressure drop through the collector is relatively small, being in the range of 1.5-in. water gage; (*e*) power consumption is less than for high-velocity cyclones or cloth filters, (*f*) the machine can be used for many dusts, particularly those of high specific gravity and <200-m. Most industrial dusts, however, contain too great a percentage of fine particles to be handled satisfactorily by this type of apparatus alone. Disadvantages: Where there is a silicosis hazard, the low-efficiency collector does not remove enough dust. If the recovered dust has value, more complete collection is justified. The extremely fine sizes discharge as a cloud, if any appreciable amount is present.

Separation coefficient (centrifugal coefficient) C_G of a centrifugal machine is defined as the ratio F/G, where F is the centrifugal force acting on a particle, $= GV_p^2/gr$ where G = weight of particle, lb., V_p = tangential velocity, f.p.s., g = gravitational acceleration, ft. per sec.^{2}, r = radius of rotation, ft., and F is in lb. Then

$$C_G = -(V_p^2/gr) \tag{17}$$

Separation coefficient of a gravity chamber is 1.0. The magnitude of the centrifugal effect and its variation with diameter of gas path and gas velocity are indicated by Table 4.

Table 4. Centrifugal coefficients in rotary gas streams

Diameter of gas path, ft.	Centrifugal coefficient (gravity = 1)	
	Peripheral velocity, 40 f.p.s.	Peripheral velocity, 80 f.p.s.
20	5	20
5	20	80
1	100	400
1/2	200	800
1/4	400	1,600

Resistance to separation is a function of the radial length of travel of the dust particle before reaching the cyclone wall, the time during which centrifugal force acts upon the particle, and its gravitational settling rate. Large particles require less time or less angular travel before reaching the wall of a cyclone cylinder than do the smaller particles. These relationships, translated into cyclone sizes and gas velocities, are shown in Table 5. A high-velocity small-diameter cyclone with relatively large depth is, therefore, most effective for fine particles. Such cyclones clean air most effectively but have low volume capacity and cause high pressure drops. They are usually arranged in parallel to make up capacity.

Large cyclones, the diameter of which is 3 to 6 times the inlet-pipe diameter, have large air capacities. Various designs of low-resistance types are available. The tangential-entry type, with the deflector arranged to avoid pinching off entry of air by the whirl, is common; this design obviates excessive back pressure. The helical-roof type serves the same purpose by deflecting the outer vortex downward. The usual form has vanes for deflecting air into the outlet whorl.

Resistance of well-designed collectors should range between 1.0 and 0.5 velocity heads. It depends to some extent on the size. For very small diameters, pressure drop over the collector may exceed 3-in. water gage.

Table 5. Relative minimum tangential gas velocities necessary to separate various dusts in cyclonic collectors

Particle size, microns	Diameter of collector, ft.					
	0.5	1.0	2.0	4.0	6.0	12.0
	Relative minimum velocity, f.p.s.					
100	....	....	0.8	1.6	2.4	4.8
50	0.8	1.7	3.2	6	10	20
20	5	10	20	40	60	120
10	20	40	80	160	240	480
5	80	160	320	640	960	2,000

Nature of cyclonic flow. The centrifugal force to which dust particles are subjected during their spiral travel around the axis of a cyclone imparts a radial separating velocity. Resistance to movement of the particle through the gas was given by Stokes as $6\pi baV$ (see Eq. 2) for a sphere moving under streamline conditions. At any point where fluid resistance is equal to the centrifugal force, $6\pi baV_S = \frac{4}{3}\pi a^3(S - p)V_p^2/gr$ (see Eq. 17), whence

$$V_S = \tfrac{2}{9}a^2(S - p)V_p^2/bgr \tag{18}$$

Formulas for cyclonic collectors

Gas volume throughput. Eq. 19 by Lissman (*37 CME 630*) is for cyclones the length of which, below the bottom of the gas inlet, is not less than approximately one diameter d, and for which the ratio e/d^2 lies between $^1/_4$ and $^3/_4$ and the ratio A/d^2 lies between $^1/_8$ and $^1/_2$.

$$Q/d^2 = Ke/d\cdot A/d^2\cdot\sqrt{HT/Pp_a} \tag{19}$$

where Q = gas volume throughput, H = draft loss through collector, T = temperature of gas, absolute, P = gas pressure at inlet, p_a = specific gravity of gas with respect to air, d = diameter of cyclone (cylindrical), e = diameter of gas outlet, A = area of gas inlet, K = a numerical constant, the magnitude of which depends upon the units.

For a given cyclonic collector: $Q = K_1\sqrt{HT/PD}$ where K_1 is a numerical constant, different from K, Eq. 19, since it contains the terms K, e, d, A.

Separating velocity. Anderson (*16 AIChE 69*) and Shepherd and Lapple (*32 IEC 605*) give the following modified form of Eq. 18, disregarding gas density p.

$$V_S = D^2\theta^2Sr/Kb \tag{20}$$

where θ = angular velocity of gas stream, r = radius of curvature of gas stream, D = diameter of dust particle, S = density of dust particle, b = viscosity of gas, and K = a numerical constant. Stokes' law is assumed to hold.

Particle travel for a given distance of gas travel. The same authors (*ibid.*) evaluate radial particle travel in terms of rotary gas path as follows:

$$s = D^2lV_pS/Kb \tag{21}$$

where s = length of radial travel of particle, and l = angular length of gas travel. Stokes' law is assumed to hold.

Minimum particle size collectible. Anderson (*loc. cit.*) and Rosin, Rammler, and Immelman (*76 ZvDI 443*) give the following equation:

$$D_{\text{min.}} = \sqrt{Kwb/lSV_p} \tag{22}$$

where w = width of gas stream.

Efficiency of collection. No basis for estimating efficiency is standardized. Some manufacturers guarantee to recover a specified percentage of a given dust; others a specified percentage of all of a given dust coarser than a specified size. The difference in these two bases is apparent when they are applied to the materials of Table 6.

A warranty to collect 20% of all dust would be a very much simpler problem in case of the cement, since it would involve

Table 6. Size distribution of two dusts

Micron sizes	Fly ash		Portland cement	
	Weight, %	Per cent. collected	Weight, %	Per cent. collected
>5..........	72	89	74	99+
>10..........	43	97+	64	95
>20..........	21	99	43	99+
Total solids....	100	80	100	83

taking less than half of the >20-μ fraction, while it would mean taking 95% of that fraction of the fly ash. A warranty to take 90% of the >20-μ. fraction would mean recovery of only 18.9% of the total fly ash, but 38.7% of the cement.

Fractional-efficiency method (*Buell Eng. Co.*) bases the efficiency rating on the percentage of material which has a settling velocity in excess of some given value that is collected. Thus Fig. 10 gives curves representing the efficiencies thus calculated of a given collector on three dusts of different specific gravities; the efficiencies are the same for separations at 8.2-μ for dust C having a sp. gr. = 1.0, at 10-μ for dust A with a sp. gr. = 2, and at 14.1-μ for dust B with sp. gr. = 3.

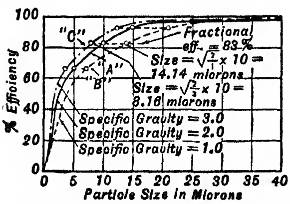

FIG. 10. Fractional efficiency.

Standard cyclone dust collector is shown in Fig. 11. Table 7 gives the important dimensions and gas-volume capacities for selected sizes. The design seeks to overcome difficulties from moisture and the tendency of fine powdered material to pack, and yet effect maximum collecting efficiency possible with a simple, relatively compact design. This type of machine, modified if desirable to suit special conditions, is used generally to recover mineral dusts. It is the type most used when highest efficiencies are not required.

Van Tongeren cyclone (Fig 12) is designed to minimize re-entrainment of dust already precipitated on the outer wall, by providing an enlarged section, beginning at a, which serves to reduce the radial velocities in the ascending vortex, and by providing a shave-off outlet b in this zone where a heavy concentration of precipitated dust necessarily passes down toward the bottom outlet. The inlet is placed in the zone c where the upper and lower eddies meet, and where, therefore, the secondary flow component is definitely outward; the double eddy is thus encouraged and is claimed to assist separation. The eddy d occupies nearly the entire annular space between the concentric discharge duct e and the outer casing. A large portion of the dust separated by centrifugal action is carried upward and accumulates under the top plate. This also is shaved off through another port b. Both shave-offs connect via by-pass f with an inlet port g, which reintroduces the dust at a point where the wall currents have a downward direction; this aids gravity in producing flow to the discharge at h.

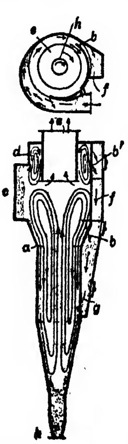

FIG. 12. Van Tongeren cyclone.

Test results by Buell Engineering Co. on a 36-in. (diam.) Van Tongeren collector are given in Table 8.

The net effect of installation of four of these collectors on kilns was a draft loss of 2 1/2- to 2 3/4-in. water gage.

Parallel arrangement of six cyclones is shown in Fig. 13. The inlets a lead from a common duct; the collectors discharge dust into a single bin, and clean gas flows into two branches of a common overhead duct.

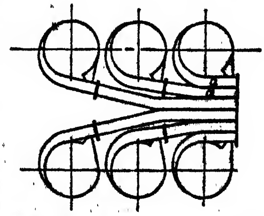

FIG. 13. Parallel arrangement of cyclones.

a No condensate.

Multiclone collector (Fig. 14) comprises an assembly of cyclones of small diameter (item *A*). Dust-laden gas enters via duct *a*, under the sloping divider *b*, and is distributed to the tops of the individual tubes of the battery around gas outlets *c*. The downflowing stream is caused to whirl by vanes *d*. Precipitated dust collects in the common hopper *e;* more or less cleaned gas from the battery discharges into chamber *f* and leaves via duct *g*. In another form, the gas inlet to individual tubes is tangential or involute. The assembly may be made with the tubes horizontal. Tubes are ordinarily 6- or 9-in. diameter. Individual units are made as small as is consistent with cost, since, as is shown in Eq. 22, the size of the particle completely collectible is proportional to the square root of the width of the gas path (or radius of collector), and Eq. 19 shows that the gas-volume capacity is proportional to the square of the diameter. As is also evident from Eq. 22, the size of the minimum particle completely collectible is inversely proportional to the square root of the gas velocity. Since this velocity depends primarily on the pressure differential, *H*, across the collector, and since the smaller the particle collectible, the larger the proportion of all the particles carried by the gas that will be collected, the collection efficiency ordinarily increases with increasing pressure drop.

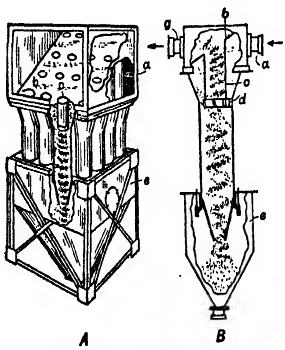

Fig. 14. Multiclone.

Performance data, furnished by the manufacturer, are given in Table 9. (See also Table 6.)

Table 9. Data on Multiclone installations (*from Western Precipitation Co.*)

Type of plant, or material treated	Gas vol., c.f.m.	Temp., °F.	Draft loss, in. H_2O	Type and size of unit	Collection efficiency, %

Power consumption of cyclonic equipment consists principally of the cost of moving the gas against the pressure differential of the collector. Assuming a 50% fan efficiency, the power required is approximately 0.3*H* hp. per 1,000 c.f.m., where *H* is the pressure differential in inches of water. Since a lesser percentage of the dust will ordinarily be collected at 1-in. pressure differential than at 3-in., the power consumption per unit weight of dust collected will not decrease in proportion to a decrease in pressure differential.

Thermix tubular collector (Fig. 15) is cylindrical throughout its length. It consists of an inner tube *a* and an outer tube *b* between which the separation is effected. The outer

tube is 6- or 9-in. diameter. Two long narrow slots *c*, opening into the outer tube from a plenum chamber *e*, impart tangential flow to the gas in the annular space *d*. Solid particles deposit on the outer wall of *d* and move downward by gravity and under the impulse

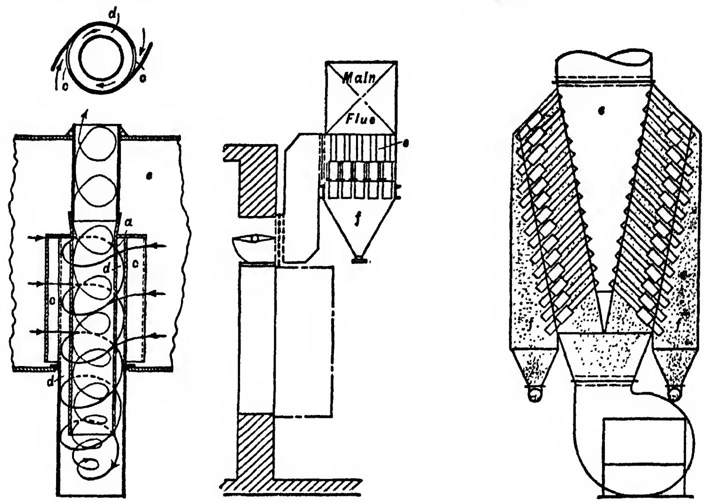

FIG. 15. Thermix collector.

of the downward component of the gas whorl in the annular space, which downward flow is enforced by the fact that the clean-gas outlet is upward through inner tube *a*. Dust discharges into closed dust chamber *f* at the bottom.

Sufficient capacity is secured by multiplying tubes in parallel (items *B*, *C*). Item *B* shows an arrangement in a boiler flue; in item *C* the tubes are set at an angle in a fan-discharge flue, in order to conserve space.

Collection efficiencies are said to range between 85 and 90% on pulverized fuel dust, with a draft loss of approximately 2 in.

Performance characteristics of high-velocity cyclones are given in Fig. 16. Item *A* shows the effect of diameter on resistance and separation for given gas throughputs;

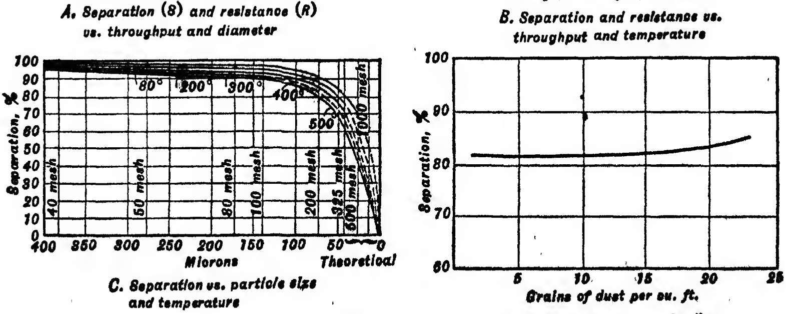

FIG. 16. Performance characteristics of high-velocity cyclones.

item B correlates separation, resistance, temperature, and throughput; item C shows the effects of particle size and temperature on separation; and item D the effect of gas loading on separation.

Scroll-type collector (Fig. 17) utilizes a high-speed fan (5,000 to 10,000 f.p.m. peripheral speed) to initiate the whirl of dirty gas in an enclosure resembling the housing of a centrifugal fan with the involute augmented to 1 3/4 turns. Gas inlet is at the center of fan rotor a. The fan discharges into involute b. After having completed 1 1/4 to 1 1/2 turns of the involute, the main gas stream is reasonably denuded of dust, which is concentrated in the peripheral layer. This is drawn off, to the extent of 10 to 20% of the volume of the stream, through a peripheral outlet c, the aperture of which is controlled by an adjustable damper d. Cleaned gas is discharged at e; the drawoff is sent to a cyclone f, which separates the bulk of the dust, returning its gaseous effluent to the inlet of the scroll.

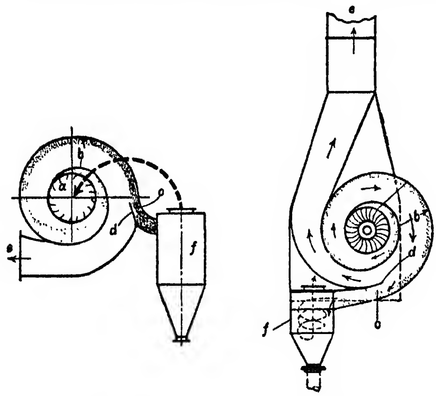

FIG. 17. Scroll-type dust collector.

Efficiency of the scroll is said by the manufacturer to be 90%; that of the cyclone from 50 to 90%; over-all efficiency, 81 to 89%. The apparatus is recommended for complete collection in connection with low-pressure conveying and exhaust systems.

Mechanical-type dust collectors

These machines utilize the specially conformed blades of an exhaust fan as the dust-precipitating surface. As a result they can be made into relatively compact units.

Roto-clone (Fig. 18) comprises a disk-shaped fan B, rotated at relatively high speed, to which dusty gas is fed through central duct A. The heavier dust particles precipitate on the disk; lighter particles are precipitated on the advancing faces of blades C, mounted on the inner surface of the disk. Centrifugal force moves the precipitates toward the rim of the disk, the blades being so contoured as to converge the stream of precipitate and lead it to a narrow annular opening through which it passes onto blade D, from which it discharges into a dust chamber E, while the clean-air stream passes on into scroll F. Blades D maintain a rotary current in E which sweeps the dust-laden stream through duct G into gas-tight hopper H, where the bulk of the dust settles and the substantially denuded gas recirculates through port K into chamber E.

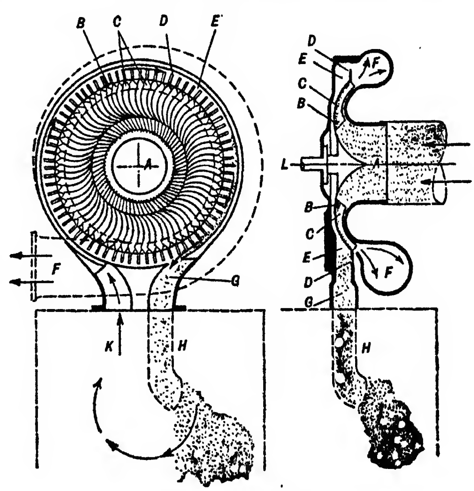

FIG. 18. Roto-clone.

Performance characteristics are those of a forward-curved blade fan; the operating range is that of a medium-pressure exhauster. The relationships between pressure, air volume, and horsepower follow the standard laws of fan performance. RATINGS are: Small unit, at 2-in. static pressure, 150 c.f.m. for 0.12 hp., and at 10-in. static pressure, 300 c.f.m. at 1.65 hp;. large unit, at 2-in. static pressure, 8,000 c.f.m. for 5.8 hp., and at 10-in. pressure, 20,000 c.f.m. for 75 hp.

Dust-separating efficiency varies with the nature and concentration of the dust, but in every case is appreciably higher than can be obtained with a cyclone or similar mechanical separator. The collection efficiency is not affected by changes in air volume or operating speeds, and remains constant over the

entire pressure-volume range. In general, 70 to 80% removal by weight is effected with dusts met in foundries and mines. It is reported that efficiency drops rapidly on 10-μ and finer particles. It is argued that since dust collection occurs as an incident to the work of the fan as an exhauster, a power saving is effected equivalent to the static losses in other types of collectors.

Wet Roto-clone (Fig 19) uses a water spray in conjunction with an impeller. The machine is of the same general construction and operating principle as the dry form (Fig. 18), but dust-laden gas entering through duct E is sprayed in zone F by water from pipe G. Rotor Q is a flat disk with a central cone and peripheral blades H. Lead-off tips K, specially conformed to minimize spraying, deliver sludge into passage L and thence through duct N into the collecting hopper. Cleaned air discharges through scroll M. If desired, the dusty gas may be run first through pipe A into a scroll in the upper part of the dust hopper; here it receives a preliminary spraying, and the coarsest material is dropped out, saving wear on the fan.

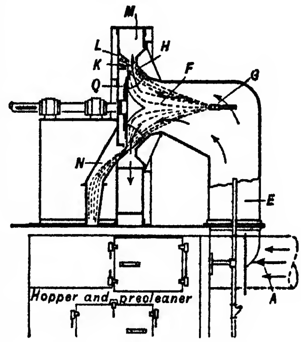

FIG. 19. Wet Roto-clone.

RATINGS range for the small unit from 1,000 c.f.m. at 2-in. water-gage pressure, requiring 1 hp., to 1,300 c.f.m. at 10-in. water gage requiring 5 hp.; for the large unit, from 30,000 c.f.m. at 2-in. water gage, requiring 35-hp., to 37,000 c.f.m. at 10-in. water gage, requiring 140 hp., without a precleaner; when the precleaner is used, the maximum pressure available is 7-in. water gage and power is increased about 50%.

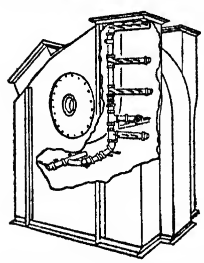

FIG. 20. Spray arrangement for Hydro-volute scrubber.

Hydro-volute scrubber comprises a special fan with a water-spray assembly (Fig. 20) in the volute inlet boxes, to wet down the dust. A strong vortex action is maintained as the air passes to the fan impeller, which throws out much of the wetted dust and water and prevents them from entering the fan. For the finest dusts, a high degree of agitation in the presence of a water spray is necessary. For this service a two-element fan is used—the air with its dust and water content enters at the center of one side of the wheel, and is discharged at the center of the other wheel.

5. AIR (GAS) FILTERS

When dusts are very fine and/or the loading is light (1 to 10 gr. per cu. ft.), collection is frequently effected by filtration. The usual filter medium is some type of cloth. Two systems of cloth mounting are used, *viz.*, tubular bags, and rectangular sheaths covering a screen-frame support. Filtration and discharge of pack are intermittent; continuous operation is achieved by use of multiple units with manual or mechanical switching.

Tubular filter (Fig. 21) comprises from 1 to about 600 long (4- to 24-ft.) cloth bags a of small diameter (3- to 9-in.), closed at the top and open at the bottom, hung from a shaking frame b in a chamber c, closed at the top, having inlet pipe d and outlet pipe e let into the walls, with a gas-tight baffle f between; and closed at the bottom with a tube sheet g, onto the sleeves of which the lower open ends of the bags are clamped. The baffles f and tube sheet g thus serve as a diaphragm to separate the dusty-air plenum chamber h from the clean-air chamber c. Hopper i forms a sealed closure for the bottom of chamber h.

In operation, dusty air enters at d, is deflected downward into chamber h, where it may drop some dust, and then passes through tube sheet g up into bags a. The gas passes through the bag walls into chamber c, depositing dust on the inside walls of the bags, and passes out through duct e. Intermittently the supply of dusty air is shut off, and shaking device b is operated for an interval to dislodge the dust pack, which drops through the tube-sheet holes and through chamber h into hopper i, from which it is discharged as desired by a dust lock.

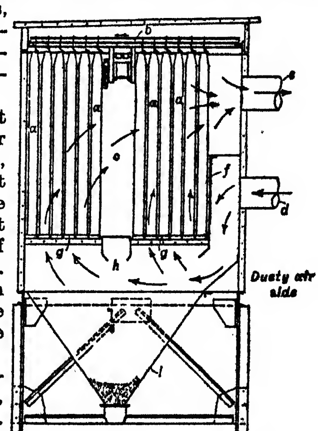

FIG. 21. Tubular dust filter.

Screen-frame filter (Fig. 22) has the cloth filter sheaths, which are flat rectangular bags *a* open at the top, slipped over screen frames *b*, and clamped together at the open edges, as shown in item *B*, so that the clamped edges close off the dust-filled chamber *c* below from the clean-air chamber *d* above. Dusty air enters at *e*, circulates upward around the frames in the interspaces *c*, air passes through the bag walls into the interior of the bags, depositing dust on the outside, and passes upward in the spaces *f* (item *B*) maintained between the bag walls by the coarse screen, and thence out at the top into chamber *d* and outlet *g*. The frame *h* supporting the screen frames is jarred at intervals (with feed supply shut off) by a manual knocker *i* and anvil block *j*, or mechanically by manual or automatic control. Dust drops into hoppers *k* and is discharged through the customary dust lock. Capacity is obtained by multiplication of frames ranging in size from 1 sq. ft. to about 60 sq. ft. each side.

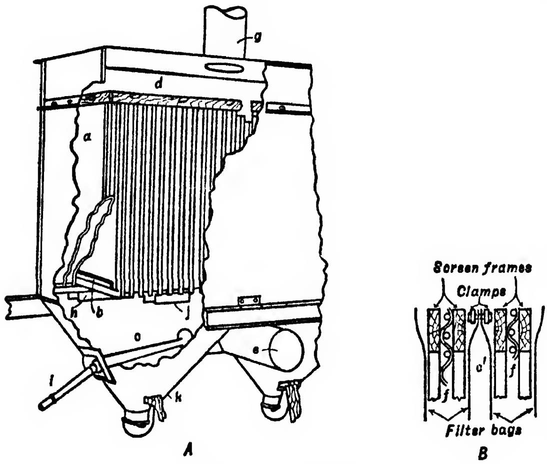

Fig. 22. Frame filter.

Shaking intervals vary with the rate at which back pressure develops, which depends, in turn, on the fineness of the dust and the dust load; intervals range from 5 or 10 min. to 4 or 5 hr. Presettling is often used to reduce excessive loads. Frequency of interval and thoroughness of dust removal are inversely related for the reason that the dust pack rather than the filter fabric is the effective separating surface (see Sec. 16, Art. 2).

Fan is placed on either the inlet or the outlet side; the latter placing is usual with abrasive dusts, in order to save fan wear.

Cloth. Different cloths are used according to the service. Cloth should always be the most permeable that will remove the dust and stand up in service. PERMEABILITIES (and relative pore sizes) are indicated by Fig. 23. Drop for felts is 0.004 to 0.006 in. of water per f.p.m. of mean through-cloth velocity; for Canton flannel, 0.012 to 0.020 in.; for vacuum-cleaner cloth, 0.019 to 0.060 in. GAS VELOCITY through the filter is normally in the range of 2 to 4 f.p.m., *i.e.*, 2 to 4 c.f.m. passing each square foot of filtering area (called the RATIO). Ratios as low as 0.5 are used in filtering fumes that tend to blind the cloth. Cement, feldspar, and silica dusts are filtered at ratios of 1.5 to 3. Higher ratios may be employed; they result in high resistance and rapid deterioration of filter cloth.

LIMITING TEMPERATURE for cotton filter fabric is approximately 175° F. This limit may be somewhat extended by using wool fabric; considerably with asbestos fabric, but at some sacrifice of filtering efficiency. If the gas contains moisture, temperature must be maintained above the dew point to prevent condensation and sludging of dust on the cloth. Deleterious reaction on the fabric by the gas must be avoided. Fabrics are sometimes fire-proofed.

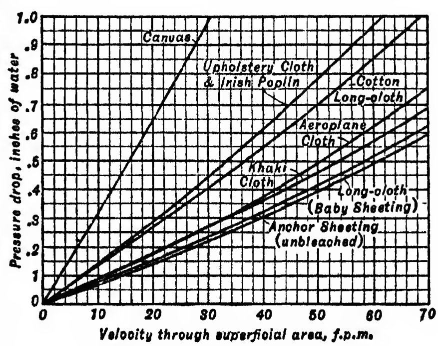

Fig. 23. Permeabilities of filter cloths.

Spark screen of wire is installed in a compartment ahead of the filter-cloth section when there is a possibility of sparks or incandescent materials being introduced; this screen is usually fitted with a rapping mechanism to shake down dirt and lint.

Clean-air filters are placed on air-feed lines designed to supply dust-free air. They constitute a considerable variety of filtering media, which are mounted as diaphragms across the air duct. The simplest are fine-mesh SCREENS, which, of course, remove initially only lint, and liquid droplets (oil) which impinge directly on the screen wire. After a coating of lint has built up, efficiency increases somewhat, since flow is rendered more turbulent and impingement surface (the lint strands) is increased. A structure built

of ZIGZAG VANES works on the same general principle as the screen, but, having greater depth along the line of flow, it offers more impingement area after turbulence has been initiated. MATS of fibrous material held between coarse screens, and of granular material between finer screen, embody the same turbulent-impingement principle. WATER SPRAYS between diaphragms of plane or zigzag vanes (SCRUBBER FILTERS) are designed in the hope that the pores in the water curtain will be small, that the spray will induce high turbulence in the air stream, and that the dust will adhere to the water droplets on which it impinges. All three hopes are largely chimerical so far as fine dust is concerned. OIL CURTAINS are formed by trickling oil over screens and the like, in the expectation that the oil will wet and hold dust particles better than water. It will, but since it cannot be discarded as freely, the installation must include means for recirculation, cleaning the oil, and the like, and the oil curtain itself must either be highly porous with respect to the finest dusts or the pressure drop must be such as tends to emulsify oil in the air stream.

6. SPRAY WASHERS

A spray tower is a chamber, elongated vertically, within which dust particles and liquid droplets are brought into contact by causing the liquid to trickle downward over finely irregular surfaces, countercurrent to a stream of gas.

The size of the liquid droplets is regulated in accord with the size of suspended particles, on the principle that the interstices between drops for a given liquid loading of the gas are smaller the smaller the drops. Separation is essentially inertial, and is dependent, therefore, on effecting and maintaining the highest possible relative movement between droplets and the gas stream. If both droplets and particles move with the gas stream, contact between them is slight.

Removal of liquid from the cleaned gas is also a necessary part of spray-tower operation. Inertial or gravitational methods are ordinarily used; their effectiveness is in inverse relation to the effectiveness of spray formation.

Packed towers, in which a suitable filling material is closely packed on suitable supporting grids, are the simplest form of spray tower. The filling materials are commonly broken rock, brick, or metallurgical coke, or specially conformed tile. Liquid is distributed over the top of the packing and in trickling down meets streams of gas rising through the interstices. The splattering of the falling liquid streams on the solid surfaces and the frictional effects of the gas streams break the liquid into droplets of a size dependent upon the surface tension and viscosity of the liquid and the gas velocity. The tortuous path of the gas induces high turbulence, if the streams are of sufficient velocity, which produces the desired inertial effects.

DISADVANTAGE of packed towers is the high pressure drop through them. Most modern towers reduce pressure drop by increasing the cross-section and directness of the gas path, and make up for this by imparting high rotational velocity to the stream as a whole.

Multi-wash collector (Fig. 24) consists of a cylindrical sheet-metal tower *a* with bottom tangential gas-inlet duct *b*, a plurality of so-called impingement plates *c*, a liquid-inlet pipe *d*, and a tangential gas-outlet pipe *e* at the top.

The principle of the device is to cause rapid rotary travel of the gas by reason of the tangential inlet and outlet ducts and suitable curvature of the vanes on the impingement plates, thus causing the general path to be a rising spiral; at the same time to wet down all interior surfaces, and to interrupt the downward flow of liquid along them frequently, so that the rapid counterflow of gas across the surfaces, particularly at the points of interruption, will break the liquid into fine droplets and disperse it as a mist throughout the gas to be cleaned. The end sought is to produce maximum dust-collecting surface.

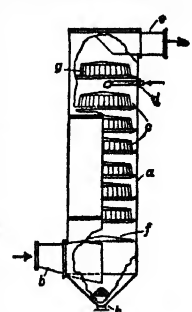

FIG. 24. Multi-wash spray tower.

Action in the Schneible apparatus pictured consists of rough separation in the wet cyclone comprising the bottom section of the tower under the plain baffle *f*; thereafter more or less of the sought-for mist formation occurs in the plates *c*, with accompanying dust impingement against the wetted walls, and, what is more important, against the mist droplets; an attempt is made to separate mist in the top vane-plate by the same impingement principle, and there is final discharge of cleaned gas through *e*, and of a liquid sludge through a valved bottom outlet *h*.

Manufacturer's data. Diameters of tanks range from 2 1/2 to 10 1/2 ft. with corresponding lengths from 12 to 43 1/2 ft., and corresponding capacity ranges from 1,500 to 30,000 c.f.m. of gas. Wash-liquid requirement is 3 gal. per 1,000 cu. ft. of gas. Loss of water by evaporation in air cleaning is said

to be about 3% of the flow. Sludge liquid may be cleaned for re-use by the usual methods of liquid-solid separation (Secs. 15, 16). Pressure drops vary, according to the number of plates, from 2 1/8- to 3 1/8-in. water gage.

Freyn tower (Fig. 25) has a simple wet-cyclone section *a* at the bottom, a trickle section *b* of wooden grids through the center, and a second cyclone section *c* at the top wherein the gas whorl is induced by high-pressure tangential sprays and a spiral baffle, and vertical vanes *d* on the periphery act as impingement plates and to increase turbulence.

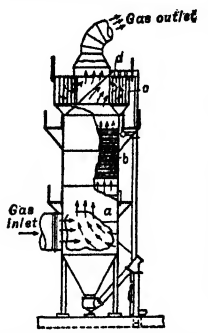

Fig. 25. Freyn spray tower.

Performance on blast furnace gas is said to be reduction of solid content to 1 gr. per cu. ft. with a consumption of 20 to 30 gal. of water per 1,000 cu. ft. of gas.

Brassert tower, developed primarily for blast-furnace fume, contains, in order from bottom to top, a perforated conical baffle, a series of high-pressure spray nozzles and stationary spiral passages, a set of baffles, a droplet eliminator, and an expansion chamber. Manufacturer states that water requirement is 12 gal. per 1,000 cu. ft. of gas washed; that total pressure drop is 24.5-in. water gage; that the outlet gas is 5° F. above inlet-water temperature, and contains 0.015 gr. of solid per cu. ft. of gas, 82% of which is $<2\ \mu$; that the power required for high-pressure water is 1.7 hp. per 1,000 cu. ft. of gas per min., and that the total power consumption is 4.5 hp. per 1,000 cu. ft. of gas per min.

Horizontal spray washer (Fig. 26) consists of a series of vertical perforated baffles *a* and *b* set across a horizontal duct, with sprays *c* arranged to impregnate the chambers ahead of the baffles with liquid droplets. Flooding nozzles *d* are designed to maintain a curtain of liquid trickling down across the baffles. Water is recirculated from the clean end of the tank *f* through a pump taking suction on outlet *e*. Exhaust fan *g* takes suction on the scrubber. The number of plate banks depends upon the duty. Pressure drop per bank is 1/4- to 1/2-in. water gage. Flooding water is supplied at 3- to 5-lb. pressure; spray water at 20- to 25-lb.

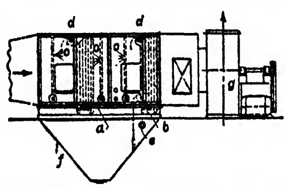

Fig. 26. Horizontal spray washer.

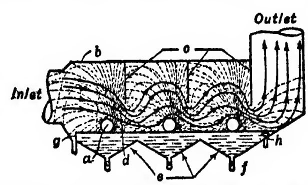

Fig. 27. Hardinge rotor-spray washer.

Rotor-spray washer (Fig. 27) consists of a light-weight hollow water-tight cylinder *a*, 12 in. in diameter by 4 ft. long, mounted on a high-speed shaft so as to be partly immersed in a body of water in *e*. The water film adhering to the revolving drum is thrown off in the form of a dense spray. Spraying capacity is controlled by the depth to which the cylinder is immersed. One or more rotors are mounted in a horizontal gas duct *b* in such a way as to force the gas stream to pass through the body of spray. Baffles *c* constrict the stream and force countercurrent travel through the zone of maximum spray velocity at *d*. Droplets carrying solid fall into tank *e*, where some sedimentation occurs. The coarser solids are drawn off periodically through spigots *f*; finer solid overflows weir *g*, water being supplied at *h* to maintain overflow.

A 1×4-ft. rotor requires a 1-hp. motor and sprays 150 g.p.m. of water. Pressure drop is 1/8- to 3/8-in. water gage.

The device has utility also in gas absorption and in washing out some liquid-in-gas emulsions. The method of spraying is superior to a nozzle for slurries containing abrasive solids or coarse fibers.

7. ELECTRICAL DUST PRECIPITATION

Electrical precipitation depends upon the fact that a corona of gas molecules moving at very high velocity is formed around conductors of small radii of curvature when these are charged at high voltage and that collisions between these molecules result in ionization. When a grounded conductor is placed near the first, the ionized molecules stream toward it and discharge. If the gas in the intervening space carries dust particles, those with which the ionized gas molecules collide become themselves charged, if they have any

conductive capacity, and thereafter act themselves as ions and travel, at rates that vary directly as the number of charges that they carry and inversely as their masses, toward the grounded electrode. The number of gaseous ions formed is very large; hence the sweeping of the intervening gas space is thorough.

Pipe-type electric precipitator (Fig. 28) comprises essentially the grounded tubular chamber a, formed of conducting material, through which gas is flowed from bottom to top; and the suspended charging wire b, which is energized through a rotary converter c or other form of rectifier, via step-up transformer d from an a.-c. line. Dust precipitated on the inner wall of a is held by the pressure of the arriving swarm of ions and ionized particles until enough has precipitated and packed for gravity to become effective to cause it to fall and discharge at e. A number of such tubes enclosed in a tower which serves both to lead gas through the battery and to protect the high-tension equipment from weather and from human contact comprises a unit.

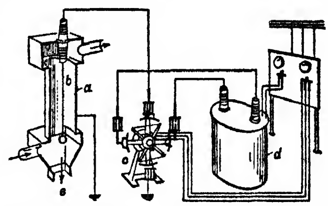

FIG. 28. Pipe-type electric precipitator.

Collecting electrodes may be parallel metal plates or screens, or rows of rods or wires; with the perforate collectors the gases may be passed either parallel or perpendicular to their planes.

Tubes are usually 6 to 12 in. in diameter and 9 to 15 ft. long. Materials of the collector electrodes are made corrosion-proof against the collector atmosphere and the precipitated material. In some cases the collector electrodes are imbedded in a protective cover of cement.

Capacity depends upon rate of charged-particle travel and the distances that such particles must travel before precipitation, as well as upon the completeness of precipitation demanded (E). The relation between E and the time t that gas remains in the field is given by the equation

$$\log (1 - E) = t \log K \tag{23}$$

in which the precipitation constant K depends upon the type of equipment and the character of the suspended material, and ranges from 0.05 to 0.50 under normal conditions, but is always less than 1.0.

Efficiency may be made anything that is desired, but the size of precipitator necessary increases very rapidly for efficiencies above 90%. For discussion of economic size see *16 AIChE 69; 106 A 316.*

Draft loss is usually less than 1/2-in. water gage.

Cost of apparatus for cleaning atmospheric air of low dust concentration is about 15¢ per c.f.m. capacity (1943); the range for dust, fume or mist collection is from 20¢ to $1 per c.f.m. capacity, depending upon the efficiency desired and the materials of construction necessary. OPERATING COST is from 1¢ to 15¢ per 100,000 cu. ft.

Applicability. The apparatus is currently used at gas temperatures as high as 1,200° F., and for mists as corrosive as those of the strong inorganic acids.

Sonic flocculation. Fine dusts, smoke, fume, and fogs can be flocculated by high frequency sound, whereupon separation may be effected by gravitational or inertial methods. No commercial apparatus is available. Experimental work is described by St. Clair (*3400 RI 51; 18 MMt 244*). FREQUENCIES used in the experimental work ranged from 10,000 to 20,000 cycles per sec. (the upper audible into the supersonic range of wave length). The apparatus for sonic flocculation consisted of a vibrating-piston sound source coupled to a resonant enclosure. The gas containing fine particles entered the resonant enclosure through rings of holes at the top and left through similar ports at the bottom. St. Clair advances the theory that the agglomerating effect of a sound field can be attributed to the increased effective diameter of each particle as a result of hydrodynamic forces set up between particles when the medium is vibrating between them. Also, he speculates that when the velocity in the flocculating chamber is low, radiation pressure may be effective. The radiation pressure acting on a small sphere suspended in a vibrating medium is of much greater magnitude for a standing wave than for a progressive wave. St. Clair shows by mathematical deduction that the force is proportional to the volume of the sphere and to the energy density, and is inversely proportional to the wave length. It is equal to zero at both the node and antinode, reaching a maximum midway between, and it acts in such a direction as to urge the particle toward the antinode.

8. DESIGN OF DUST-COLLECTING SYSTEM

A dust-collecting system comprises the collecting and conveying system and one or more separating apparatus of the types described in Arts. 3 to 7. The collecting and conveying system consists of (a) collecting openings or hoods, placed and conformed to surround the dust-making center as completely as is consistent with inflow of gas for conveyance; (b) ducts for transport of the dusty gases to the separator; and (c) means, usually a fan or fans, to move the dust-laden gas.

The conveying capacity of a gas depends primarily upon its velocity. (See Eqs. 14, 15, 16, and Fig. 4.) Resistance in the conveying system varies almost directly as the weight of material conveyed. If resistance in a system builds up to the point that the pressure differential is insufficient to maintain critical conveying velocity, the system deposits solid in the lines, which is a frequent cause of trouble in poorly designed collecting systems.

Requirements. The important requirements to be satisfied are: (1) Hoods, ducts, fans, and collectors should be of adequate size. (2) Air velocities throughout should be sufficient to convey the suspended material under all loading conditions contemplated, with additional allowance for normal contingencies. (3) Hoods and ducts should not interfere with the operation of a machine, should be readily removable to permit convenience in repair, and should have adequate inspection doors. (4) The system should do the required work with minimum power consumption. This means, among other things, that velocities should be kept down to the minimum safe value.

Actual design usually starts with a scale floor plan of the machinery to be served, on which should then be marked the probable dust loads and/or the probable minimum suction, velocity, or volume at each dust-making center. Next, sketches of the hoods necessary at these various points should be made, these being the starting point in the detailed design. Thereafter design of the conveying system comprises determination of branch lines from hoods to main ducts, of the main ducts, and of the fan.

Suction openings

The effectiveness of a suction opening depends upon its proximity to the source of dust, the face velocity (average inward velocity across the intake section), the size of the dust particles, and their state of motion.

Proximity. The velocity of approach to a suction opening decreases rapidly as the distance from the face increases. When normal flow toward the face is unobstructed, velocity of approach V_A is given by the equation

$$V_A = 0.1Q/(x^2 + 0.1A) \tag{24}$$

where Q = volume of gas entering, c.f.m.; A = area of face, sq. ft.; x = distance along axis, ft., and V_A is in f.p.m. This equation also gives the volume of gas that must be flowed into a given opening for a specified velocity of approach at a distance from the face.

Item	Form of Orifice	Description	Coefficient of Entry C_e	Loss in % of velocity head h_e
a		Smooth well rounded	0.98	4
b		Flanged cone, 13° included angle	0.94	13
		Flanged cone, 30° included angle	0.90	24
c		Flanged pipe	0.82	49
d		Unflanged cone, 13° included angle	0.82	49
		Unflanged cone, 30° included angle	0.79	60
e		Unflanged pipe	0.72	93
f		Short flanged pipe, less than 1½ diameters long a	0.60	178
g		Thin-plate orifice a	0.60	178
h		Short protruding pipe, less than 1½ diameters long a	0.53	256

a Entering a large chamber.

FIG. 29. Entry characteristics of standard orifices (*after Alden*).

Face velocity. When a gas enters a suction opening there is a loss of velocity head and a reduction in cross-section of the stream. The extent of these changes depends, all other

things being equal, upon the shape of the entrance opening. Reasonably accurate determination of the numerical values of the changes have been made for typical standard orifices of circular cross-section. Values are given in Fig. 29. Values for hoods and other forms of enclosures for mill dust collection are not established, but are approximated in designing from their resemblance to standard orifices. A few experimental values given by Alden (*loc. cit.*) are shown in Fig. 30. The general relation between entry coefficient and entry losses is given in Fig. 31.

Item	Hood Type	Nearest simple orifice (Fig. 30)	Entry coefficient C_e	Entry loss, h_e, % of velocity head
a		Flanged pipe	0.82	0.49
b		Flanged pipe	0.82	0.49
c		Flanged pipe	0.82	0.49
d		Flanged pipe; chamber loss reduces C_e	0.79	0.60
e		13° unflanged cone	0.82	0.49
f		Unflanged pipe and mitre elbow (pressure measured in pipe)	0.57	2.08
		Unflanged pipe (pressure measured in hood)	0.72	0.93
g		Unflanged pipe and square-throat elbow (pressure measured in pipe)	0.61	1.69
h		Unflanged pipe and mitre elbow (pressure measured in pipe)	0.57	2.08
i		30° unflanged cone and 2 elbows (pressure measured in pipe above square-to-round)	0.71	0.99

FIG. 30. Entry characteristics of particular suction openings (*after Alden*).

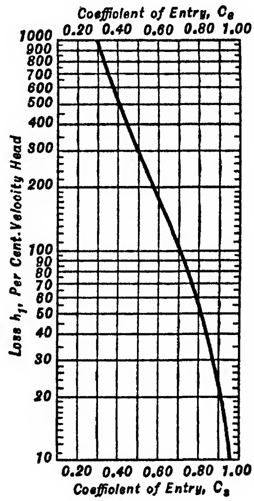

FIG. 31. Entry coefficient *vs.* entry loss (*after Alden*).

The data of Figs. 29 and 30 apply to the face at entry to the duct, not to the face of the hood. Velocity at the latter point is to be approximated by application of Eq. 25.

Size of dust particle. No definite relation between particle size and face velocity at the hood mouth has been established. Experimentation on actual dusts requires substantial reproduction of actual conditions; hence it is not done in practical design. Rather some empirical figure based on calculation of mean velocities in existing installations is adopted. When the dust itself has a velocity of escape from the point of generation, this should be utilized, if possible, in hood design; otherwise the inlet velocity must be great enough to reduce escape velocity to zero, and additionally to set up an inflow current that will transport the dust to the duct face. Hood design should, if possible, be such that the dust is projected into the region of maximum gas velocity through the hood. Recommended velocities for usual enclosures are given in Table 10.

Table 10. Recommended face velocities through top hoods and booths subject to cross drafts (*after Alden*)

Description	Velocity, f.p.m.
Canopy hood, plain	
Open, flow through 4 sides	200 to 250
Closed on 1 side, flow through 3 sides	175 to 200
Closed on 2 sides, flow through 2 sides	150 to 175
Closed on 3 sides, flow through 1 side	100 to 150
Booths, through one side	100 to 150
Laboratory hoods (door open), through door	50 to 75

Pressure *vs.* velocity. Two pressures are important in ordinary dust-conveying problems, *viz.*, static pressure and velocity pressure. The former is the push behind the gas, causing its motion; the latter, the force required to accelerate the gas. The sum of these pressures (dynamic or impact pressure) is the total pressure of the moving air on any

object in its path. Static pressure overcomes the resistances to flow set up by the system; it decreases along the line of flow; the difference in static pressure between two points along the line of flow (PRESSURE DROP) is a measure of the resistance of the system between the two points. Static pressures are ordinarily measured by the vertical height of a column of water in balance with them (h_s); a column 1 in. high (1-in. water gage) corresponds to a gas pressure of 0.0361 lb. per sq. in. A static pressure of 1-in. water gage produces an air velocity at 70° F. and standard pressure of 4,005 f.p m. when static pressure is completely converted to velocity pressure h_v. The general relation between V and h_s is

$$V = 4{,}005\sqrt{h_s} \tag{25}$$

Values of V for different values of h_s at 70° F. and standard pressure are given in Table 11; values at other temperatures in Table 12.

Velocity head for air, on the assumption of complete conversion of static pressure to velocity head, is

$$h_v = \sqrt{V/4{,}005} \tag{26}$$

Table 11. Corresponding static pressures and velocities of dry air at 70° F. and 29.92 in. of mercury (*after Buffalo Forge Co.*)

Ducts

Friction loss always occurs in movement of fluids past rigid surfaces, such as pipe walls. In design of ducts this friction loss is calculated and added to the static head required for a given velocity in order to determine the total head required. The magnitude of friction head is given by the equation.

$$P_f = ph_f = flpV^2/2gd \qquad (27)$$

where P_f = pressure drop, lb. per sq. ft.; h_f = pressure drop in ft. head of gas; p = density of gas, lb. per cu. ft.; f = friction factor (dimensionless coefficient); l = length of duct, ft.; V = velocity of fluid, f.p.s.; g = gravity constant, f.p.s.p.s. (32.2); d = diameter of circular duct, ft.; and b = absolute viscosity, lb. per sec. per ft. The friction factor f is dependent upon whether flow is laminar or turbulent. This question may be resolved by solution of the Reynolds-number (R_N) equation

$$R_N = Vdp/b \qquad (28)$$

Graphical solution is given in Fig. 32. Viscosities of common gases are given in Fig. 33.

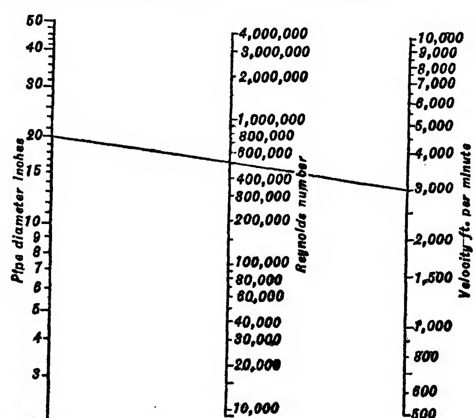

Fig. 32. Reynolds numbers for air at standard conditions in sheet-iron pipes.

The critical velocity (velocity at which the nature of flow changes) corresponds to Reynolds numbers between 2,000 and 3,000; for values above 3,000 the flow is always turbulent; below 2,000 it is ordinarily laminar. Reynolds numbers for the velocities normally met with in dust collection are well upward of 100,000; hence flow is invariably turbulent.

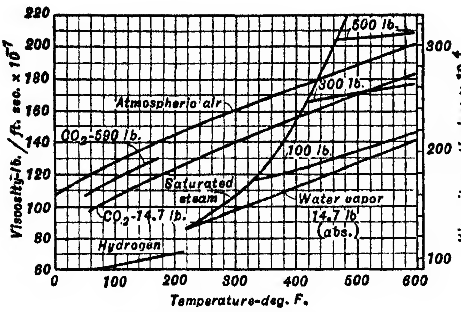

FIG. 33. Viscosities of common gases (*after Buffalo Forge Co.*).

The relation between friction factor and Reynolds number is given by the equation

$$f = ku^n/Vd \qquad \textbf{(29)}$$

where k and n are functions of the roughness of the pipe.

Fanning equation for friction loss, expressed in in. water gage h_L is

$$h_L = 0.769flpV/d \qquad \textbf{(30)}$$

where units are as in Eq. 27. Solution of the equation for air in round pipes is given in Fig. 34. The chart accords with Eq. 27 within 2% for standard air between 32° and 100° F., and friction conditions such as are found in galvanized iron ducts with normal seams. For straight smooth galvanized ducts and wrought-iron pipe apply a factor of 0.9; for riveted sheet, slightly encrusted pipe, or concrete, use a factor of 1.1.

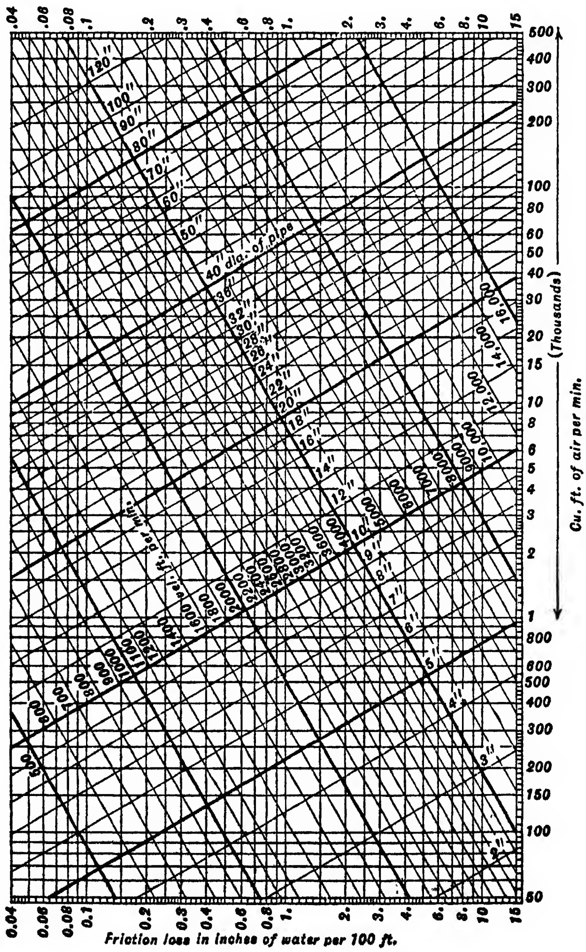

FIG. 34. Friction loss for air flowing in round pipes.

Another expression for the Fanning equation is

$$h_L = flh_v/d = \frac{1}{C} \cdot \frac{l}{d} \cdot h_v \tag{31}$$

where C = length of pipe in diameters equivalent to a loss of one velocity head h_v, and h_v, in in. water gage, = $(V/4{,}005)^2$. For all practical purposes values of C are 60 for perfectly smooth pipe, 55 for pipe normally used in exhaust systems, 50 for ventilating ducts, and 40 for rough conduits of tile, brick, or concrete.

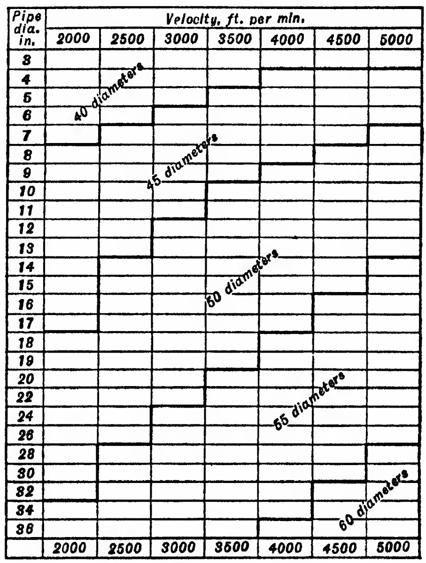

FIG. 35. Frictional resistance in straight pipes; diameters per one velocity head of pressure drop.

Engineering data for duct losses are conveniently tabulated and charted in terms of velocity heads, since duct resistances result in losses of velocity head, and the magnitude of the resistance and loss is proportional to the velocity. Such data are given for pipe in Fig. 35, for 90° elbows in Table 13, for elbows of other angularities in Table 14, for losses in mains at junctions with a branch in Table 15, and for losses in tees in Table 16.

a 45° tee and equal main and branch velocities. See Table 16 for other angles.

Velocities in dust collecting systems must always exceed certain minima which have been determined by experience for particular materials. These range from 3,000 to 4,000 f.p.m. both for powdered coal and for the usual rock dusts.

a Apply to Table 15.

Example 1. Design calculations for dust-collecting system. Fig. 36 is a diagrammatic sketch of a simple assembly of hoods and piping for collecting dust at B (conveyor junction), A (bucket-elevator boot), and C (elevator delivery chute and bin) and transferring the dust-laden air to a cyclone for collection. Material is the dust from crushed sandstone.

Conveying velocities are taken as 3,500 f.p.m.

Hoods. Sizes at A and B are fixed by the dimensions of the boxes; face areas are 4 and 6.5 sq. ft. respectively. A hood of 4 sq. ft. area is placed in a side wall near the top of the covered bin at C. All are of canopy type (Fig. 30, item a). Velocities at the faces of the various hoods will differ somewhat. The stream of material on the conveyor belt feeding the elevator tends to carry air into the boot, and the rising buckets tend to push this air up on the tight side of the housing, while the enclosed top and bin prevent ready equalization, so that a static pressure is built up in the housing. (A duct is shown connecting the head and boot housings in an attempt to equalize pressures.) Face velocity is taken as 350 f.p.m. in view of this situation. Face velocity at B is taken at 275 f.p.m. At C it is planned simply to remove enough air to maintain the bin and elevator-discharge chute under a slight vacuum; 1,000 f.p.m. is considered sufficient; face velocity is taken at 250 f.p.m. These values are about double those of Table 10 on account of the relatively heavy dust loadings.

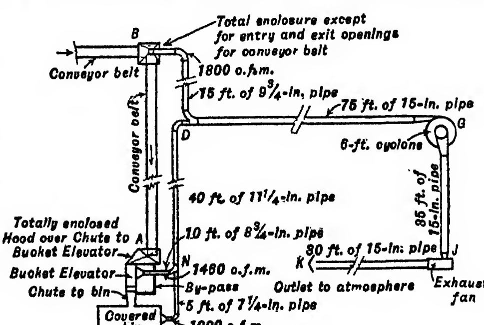

Fig. 36. Layout sketch for simple dust-collecting system.

Volumes of air entering the various hoods are, from the fundamental flow equation $Q = AV$: At A, 1,400 c.f.m.; at B, 1,788 c.f.m.; at C, 1,000 c.f.m.

Entry losses. The canopy-type hood has an entry coefficient of 0.82 and an entry loss of $h_e = 0.49h_v$ (Fig. 30).

Required static pressure to produce a velocity of 3,500 f.p.m., assuming complete conversion to velocity head h_v, is $h_s = (3{,}500/4{,}005)^2 = 0.76$-in. water gage (Eq. 25). In order to overcome entry loss there must be a residual static head at this point of $h_v + h_e = h_v(1 + 0.49) = 0.76(1.49) = 1.13$-in. water gage.

Pipe areas (velocity 3,500 f.p.m.) are: Branch at $A = 1{,}400/3{,}500 = 0.40$ sq. ft. Corresponding diameter to the nearest 1/4 in. is 8 3/4 in. having an area of 0.417 sq. ft. Similarly the feeder line from B requires 0.51 sq. ft. or 9 3/4-in. pipe with an area of 0.518 sq. ft.; and that from C requires 0.285 sq. ft. or 7 1/4-in. pipe with an area of 0.287 sq. ft. From N to D (Fig. 36) the line must carry 2,400 c.f.m., requiring a cross-section of 0.69 sq. ft., 11 1/4-in. pipe, 0.690 sq. ft. area. From D to the collector the volume is 4,188 c.f.m., requiring 1.20 sq. ft. cross-section, 15-in. pipe, 1.23 sq. ft. area.

As a CHECK on these calculations, the volume in c.f.m., using Eq. 25 and the entry coefficient and residual static head from above is, for branch A: $Q = 0.417 \times 4{,}005 \times 0.82 \times \sqrt{1.13} = 1{,}460$ c.f.m. Similar checks may be applied to the other ducts.

Static pressure against exhauster is the sum $h_v + h_e + h_f + h_c + h_0$ where h_e is entry loss, h_f is the total friction loss through the longest duct line from hood to system outlet ($= ANDGJK$), h_c is the loss through the collector, and h_0 is the loss due to expansion at outlet to the atmosphere. These losses are usually calculated in terms of velocity heads. A summation is shown in Table 17. The exhauster would be selected to deliver 4,260 c.f.m. against a static head of 5.92-in. water gage.

Table 17. Tabulation of static pressures for Example 1

Item	Basis	Duct dimension			Pressure

h_0	g				0.93	
Total	h				7.80	5.92

a From Fig. 35, a length of 8 3/4-in. pipe equal to 45 diameters causes a pressure drop of 1.0 velocity head; hence the drop for 10 ft. (= 13.7 diameters) is $13.7/45 = 0.35h_v$.

b From Table 15. Take $Q_m = 1{,}460$ and $Q_b = 1{,}000$ (Fig. 36). Then $Q_m/Q_b = 1{,}460/1{,}000 = 1.46$ and h_f (interpolated) $= 0.18h_v$.

c Method as note a.

d Table 13. Assume centerline radius $= 1.5d$.

e Method of b. $Q_m/Q_b = 2{,}460/1{,}800 = 1.37$.

f From manufacturer's rating on cyclone.

g Taken as equal to entry loss in a straight pipe.

h $h_v + h_e + h_f + h_c + h_0$.

Sheet metal for ducts. Thicknesses of metal recommended for various pipe diameters and kinds of service are given in Table 18.

Table 18. Recommended thickness of sheet metal and length of lap for round ducts (U.S.S. Gage)

a Abrasive solids not in dust-collecting quantities.

b Abrasive dust from ore-crushing plants, dry-grinding and pulverizing circuits and foundries. Heavy enough for any exhaust purpose.

c Conveying sand, cement, coal or pulverized rock and abrasive solids at high velocities and in large quantities.

9. DUST-COLLECTING INSTALLATIONS

Lynn Sand & Stone Co., Swampscott, Mass.; rock, gabbro-diorite; capacity, 250 t.p.h. *Summary.* Dry crushing from run-of-quarry to concrete aggregate. All equipment enclosed, with drives outside the enclosures and doors to allow entry for service and repair. Enclosures made of plywood; those exposed to weather of WELDWOOD, commonly used for boats.

Details of enclosure, air volumes, and duct diameters are given in Table 19.

Collectors are two Parsons bag-type, shaken down every 2 1/2 hr. Dust is either loaded direct into covered trucks or transit mixers for sale as asphalt filler, or is dumped and wasted. Recovery is 6 or 8 tons per 8 hr.

Table 19. Details of dust-collecting system at Lynn Sand & Stone Co.

Utah Copper Co., Magna plant (*153 A 324*).

Apparatus in secondary crushing plant (Fig. 37). Ore from the primary-crushing plant arrives on 2 @ 60-in. inclined conveyors *1*, and is discharged at the top of the secondary-crushing pyramid into bin *2*, distributing to 4 screens *3*, grouped symmetrically about the pyramid axis. Oversize falls through chutes to hoppers *4* over 4 @ 7-ft. cone crushers *5;* undersize drops almost vertically at *6* through a large common surge bin *7*, 26 ft. high and of 10,080-cu. ft. volume, and thence through 2 ore drops *8*, onto 2 @ 54-in. belt conveyors *9*, under the bin. Cone-crusher products also discharge into surge bin *7* through chutes *10*. Free drops in the bin are 11 ft. for crusher products and 26 ft. for screen undersizes. The plant handles as much as 1,700 t.p.h.

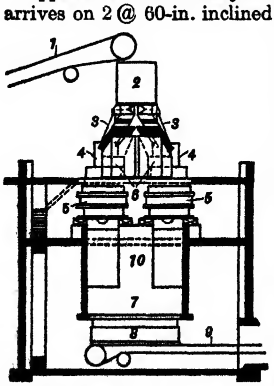

Fig. 37. Elevation of secondary crushing plant at Utah Copper Co., Magna mill.

Collecting system. The falling ore acts as a fan, pushing air downward through the system. Volume of dusty efflux was reduced markedly by closing, as completely as possible, all apertures through which in-

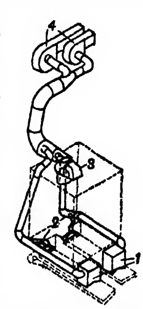

Fig. 38. Diagram of dust-collecting system for apparatus of Fig. 37.

ward leakage of air might occur. Skirted hoods were installed over the head pulleys of the primary conveyors, all chutes and hoppers were repaired and covered, the bins were rebuilt of two thicknesses of wood with tar paper between, and the exhaust ventilating system shown in Fig. 38 was installed. It discharged to a wet scrubber. Air volumes required at various inlets are shown in Table 20. Total of quantities calculated was 57,985 f.p.m.

Table 20. Air required at hoods at Utah Copper Co., Magna plant

Location	Required air flow, c.f.m.
Surge bin	40,000
Front, west ore drop	7,700
Rear, west ore drop	1,300
Front, east ore drop	7,700
Rear, east ore drop	1,300
Total	58,000

Design was made to eliminate dampers on the scores of high wear, unsatisfactory replacement, and tampering. Pipe sizes and elbow radii were adjusted in the calculations to the values necessary to maintain the desired velocities in the various branches. All piping was made in company shops; hence diameters could be specified to the nearest quarter inch. Pipe was made of tank steel, $1/8$-in. minimum thickness. Two Sturtevant No. 90 Planovane exhausters were installed in parallel, each with a rated capacity of 29,000 c.f.m. against 6.78 in. of water at 627 r.p.m., requiring 58 b.h.p. each. These discharged into a $10 \times 10 \times 30$-ft. wet scrubber, using 1.3 g.p.m. of water per 1,000 c.f.m. of air. The scrubber is operated in excess of 99% efficiency by weight (about 92% by dust count) at a 3-in. pressure drop. All fan calculations and pressure losses were based on 70° F. air at 4,500 ft. elevation.

Hollinger Gold Mining Co. (*42 CIMM 164*). The milling plant comprises 1 @ 48×60-in. jaw crusher, on the 2,900-ft. level; a surface plant with 3 No. 7 $1/2$ gyratory crushers, 3 @ 4×16-ft. trommels, 4 No. 5 gyratories, 5 @ 62×24-in. rolls, and 7 @ 5×10-ft. vibrating screens; and a grinding plant containing 4 @ 7×15-ft. wet-grinding ball mills. Capacity of the crushing plant is 420 t.p.h.; that of the grinding plant, 5,800 t.p.d.

The knotty points in the dust-elimination problem were the large volumes of air required, the low winter temperatures, the inability of cyclones to lower dust content to a point that permitted recycle of air in the building, and the difficulty in installing a dusty-air discharge from the primary crusher, located underground. The high-velocity cyclones tested collected almost all >5-μ and a considerable portion of the <5-μ material, but damp dust adhered to the cyclone shell and would not discharge by gravity. Low- velocity cyclones, with an extended cone portion, collected almost all >20-μ material but very little <20-μ. Solution of the problem involved filtering and recirculating in the underground and grinding plants, and operating the secondary-crushing plant unheated, with cyclone and room fans discharging through a 6×135-ft. stack.

Underground installation. The volume of the crusher room was 18,000 cu. ft. Enclosures were built around the feed and discharge chutes; 4,000 c.f.m. was exhausted therefrom and cleaned in a 2,000-sq. ft. bag filter, giving an air circulation of 4.5 min. The dust in the filter was 97% <325-m. and 45% <10-μ. Total dust removed approximated 2 lb. per hr. Velocity through the filter cloth was 2 f.p.m. The filter was shaken once per 24 hr. Filtered air returned to the crusher chamber had a dust count of 70 averaged over 24 hr.

Secondary crushing building. The basic principle followed in design was to enclose all dust-making centers as tightly as was economically possible, create a positive in-draft at all openings, and then exhaust ventilate the room as a whole to remove incidental dust. Enclosures were made large enough with respect to apparatus moving inside or out of them so that fan and piston effects tending to force dust outward were minimized. By-passes were also run from one end to another of housings in which there were strong drafts. Cyclone collectors were installed near and above the points they served so that coarse particles which dropped out of the exhaust streams had slopes upward of 60° to slide back on. In-drafts were set at 200 f.p.m. minimum or 100 f.p.m. excess over the estimated maximum outdraft velocity, whichever was the larger. Piping was designed for velocities of 2,600 to 3,000 f.p.m.: junctions with enclosures were made through conical thimbles giving 1,000 f.p.m. at the face. The cubic volume of the gyratory-crusher building was 152,000 cu. ft.; 11,000 c.f.m. was discharged to the stack from the enclosures, and 30,000 c.f.m. was evacuated by a 72-in. wall fan, making the air-change interval 3.7 min. The volume of the roll building was 420,000 cu. ft.; 27,000 c.f.m. was evacuated through enclosures and 60,000 c.f.m. by 4 @ 42-in. roof fans, for an air-change interval of 4.8 min. About 3 $1/2$ t.p.d. of dust, averaging 50-μ with a range of 20-$\mu \sim$100-m. and assaying 0.15 oz. Au per ton is caught in the collectors and returned to the ore stream; the air discharge carries about 600 lb. per day, assaying 0.015 oz., and is all <20-μ.

Grinding plant building was maintained at about 53° F. by the heat produced in the grinding units. The greatest source of dust was the chamber underneath the mill bin where ore was drawn onto four conveyor belts used to feed the ball mills. The belts were housed in at the feed points, and 1,000 c.f.m. was exhausted from each housing. The total combined volume of the chamber under the bin and the conveyor-belt tunnels was 39,000 cu. ft. By exhausting 1,000 c.f.m. from each of the four conveyor-belt housings and 2,000 c.f.m. from the chamber, an air change of 6 $1/2$ min. was obtained. A total of 6,000 c.f.m. was cleaned through a cloth filter and discharged to the atmosphere in summer, and recirculated to the chamber in winter. Air velocity through the filter was 1.5 f.p.m.

The feed and discharge ends of the ball mill were enclosed as tightly as possible consonant with necessary observation while operating. All enclosures were connected to a fan exhausting 6,000 c.f.m.

The moisture content of this air was too high to permit cleaning in a cloth filter; hence the air was discharged into a 3-ft. stack extending 15 ft. above the plant roof. The stack was constructed of two concentric galvanized-iron pipes with 4-in. space between filled with rock wool. A further 15,000 c.f.m. was discharged from the roof of this building for general ventilation purposes during the summer. Air change in winter was 70 min., at which an inside temperature of 65° F. could be maintained with outside air at 3° F. Air change in summer was 15 min. when exhausting 2,700 c.f.m.

Dust counts (<5-μ particles per cc.) in the roll plant were about 300 with both enclosure fans and roof fans going; 630 with enclosure fans only, against 1,440 in the winter (closed windows) and 1,025 in summer (open windows) without collection; in the underground plant the count was 110 with filter working against 1,400 with no enclosure or collection. In the grinding plant counts ranged from 60 in summer to 135 in winter; filter discharges corresponding counted 28 and 45.

Cost of installation (1938) was: secondary-crushing plant, $39,039; underground plant, $4,300; grinding plant, $15,804.

Other dust-collecting installations are described in Sec. 20, Art. 11, and Sec. 2, Fig. 29.

10. LOW-PRESSURE CONVEYING

All kinds of dry, relatively fine materials can be and are conveyed in dilute admixture with low-pressure air traveling at relatively high velocities. The general principles of design are the same as those applying in dust-collecting systems, but the required velocities are higher (Table 21), dust loadings are greater, friction losses are larger, and greater attention must be paid to wear.

Table 21. Air velocities required for low-pressure conveying

Material	Velocity, f.p.m.
Sawdust	4,000 to 6,000
Metal turnings	5,000 to 7,000
Coal, powdered	4,000 to 5,500
Ash and clinker, ground	6,000 to 8,000
Cement, Portland	5,000 to 8,000
Sand	6,000 to 9,000
Pyrite concentrate	5,000 to 8,000
Phosphate pebble	6,000 to 9,000

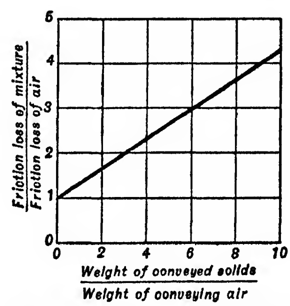

Fig. 39. Friction loss of solid-air mixtures.

Loading ranges from 1 lb. per 80 cu. ft. to 1 lb. per 15 cu. ft.; above the latter figure solid drops out. The weight that can be carried varies directly as the square of the velocity. Fine material requires more air per pound than coarse, and dense material less than light.

Friction losses increase with loading and velocity, but within the load range above stated the maximum loss is not more than 8% higher than that with air alone. Relation between loading and loss for grain is given in Fig. 39. The volumetric loading, which, with velocity, is the prevailing factor in determining frictional loss, is, of course, less with material of higher specific gravity; this tends to counterbalance the higher velocities required for the heavier materials.

Design. In general the smallest pipe that will carry the air volume at the required velocity should be used, since carrying capacity of the air increases more rapidly than power consumption. On the other hand the pressure that the fan can build and the high wear rate accompanying high velocities limit the extent to which reduction in pipe diameter can be carried.

Fans or blowers of suitable design are used either as pressure or suction exhausters. Where conveying distances are great, pressure fans may be used in tandem to step up pressure along the system. If material is of such nature that it cannot be permitted to pass through the fan blade, a suction system is used.

Piping should be laid out to avoid sharp bends and sudden changes in diameter, since these enhance abrasion. Use of rubber at points of high wear is increasing.

AIR SIZING

11. INTRODUCTION

Air sizing is the counterpart of water classification in that separation is made between solid particles by reason of differences in rate of movement in air, but it differs to the extent that the operation is invariably free-settling (see Sec. 8, Art 1), and that dif-

ferences in specific gravity are not utilized. In other words, air classification is a sizing rather than a sorting operation.

The basic phenomena employed in air sizing are the same as those used in dust collection, *i.e.*, gravitational movement and inertia. Apparatus utilizes one or the other or both in combination.

Forms of apparatus are shown in Fig. 40.

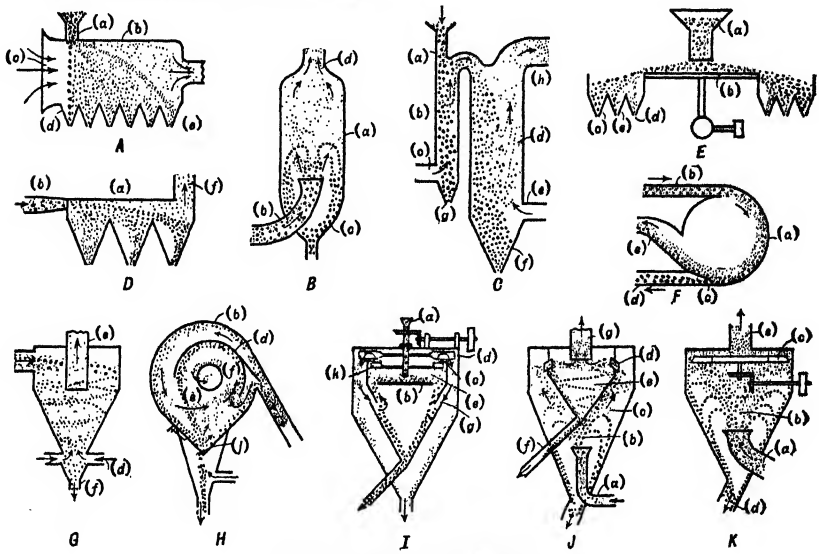

FIG. 40. Forms of air classifiers.

Gravity-type, horizontal current (item *A*). The unclassified mixture enters through hopper *a* and drops vertically into the chamber *b* where it meets a horizontal current of air entering at *c*. Coarse particles drop almost straight down into hopper *d*, whereas the finer particles are displaced horizontally according to their size, the finest being carried away in the outgoing air. The trajectories are, theoretically, the simple resultants of the drag of the air stream and gravity, applied to each particle.

Gravity-type, vertical carrying current (item *B*). Feed enters air-borne through *b*. In classifying chamber *a* the velocity of the carrying air is insufficient to support the coarser particles, and they drop out through hopper *c;* the finer particles rise with the air stream and leave at *d*.

Gravity-type, vertical introduced currents (item *C*). Unclassified material enters through hopper *a* into classifying column *b*, where it meets a stream of air introduced at *c*. The heaviest particles settle and discharge at *g;* the fines pass over into a second larger column *d*, near the bottom of which further air is introduced through pipe *e*. The finest material rises and leaves at *h*, while intermediate sizes drop out at *f*. The number of columns can, of course, be increased.

Inertia-type, rectilinear (item *D*). Air-borne feed enters chamber *a* at relatively high velocity through nozzle-type duct *b*. In *a* there is only a generally turbulent low-velocity current from *b* toward outlet *f*. Hence the trajectories of the particles are determined by their inertias and by gravity. Since all particles were moving at the same velocity on entrance, the coarser have the greater inertia. Gravitational velocities are not greatly different except for the finest sizes, so that the trajectories of the particles with the greater inertia are flatter. Thus the graduation in size shown in the figure is roughly approximated. The finest material is maintained in suspension and carried out through *f*. Item *E* shows an arrangement similar in principle, but with an initial centrifugal impulse applied mechanically by means of whirling disk *b*. Once the material leaves the plate with a relatively large radial component of velocity, its motion is as in item *D*.

Inertia-type, curvilinear (item *F*). Feed enters circular chamber *a* through tangential conduit *b*. The larger, heavier material, having the greater inertia, offers the greater resistance to change of direction and therefore crowds to the wall, displacing the smaller, lighter particles toward the center. While many of the latter resist displacement and are found along the surface, a certain amount of segregation occurs, so that deflection plate *c* divides the stream into a coarser and a finer fraction.

Combination types. Most commercial classifiers utilize both inertial and gravitational motion. In such classifiers it is usual to employ one or the other of the primary motions for a rough separation and then to follow with the other for finishing. Either operation may be supplemented by the impulse of rising air streams.

Centrifugal roughing

Cyclone type (item *G*) comprises a typical cyclone separator (Art. 4) with the rising air whorl fortified by streams of low-pressure air introduced at *d*. The effects are two-fold, *viz.*, to winnow out dust from

the coarse stream approaching bottom discharge *f* and to increase the carrying power of the rising whorl and thus carry over a coarser product than otherwise at *e*.

Volute type (item *H*) uses the centrifugal principle of item *F* for roughing, employing, however, two roughing surfaces *b* and *d*, substantially in parallel. Finishing is done by gravity working against the winnowing impulse of a rising air stream at the throat *j*, and that of the cross stream in the region *e*, as indicated. Fines are carried off by an inner horizontal whorl through pipe *f*. For control of centrifugal force see discussion of Fig. 45.

Mechanical type (item *I*) makes the initial rough separation by inertia as in item *E*, by throwing the feed stream from a whirling disk *b*. The coarse stream is then winnowed in falling over gap *g* by air circulated by fan *d*. The winnowed material is cleaned centrifugally in the whorl set up above *b* by fan *k*. Thus both products are the result of treatments by both methods of separation.

Gravitational roughing

Double-cone type (item *J*). Air-borne feed is introduced in an upward direction through *a*. On leaving *a* the velocity of the carrying current is suddenly reduced by the increase in cross-section of the stream, and coarse material drops out immediately in zone *b*. The material that passes this section is subjected to further sorting in the conical annular space *c*, which may be made of uniform or of decreasing area from bottom to top. At the top of zone *c* the stream flows inward and is deflected more or less tangentially by adjustable vanes *d*, so that a cyclone is set up in *e*. Fines discharge through *g* and an intermediate granular product drops out at *f*. No air other than that in the feed stream is used.

Mechanical type (item *K*). Air-borne feed is introduced with upward velocity through *a*, suffers gravitational roughing without additional air in zone *b*, the fines are set into whirling motion by fan *c*, and further coarse material is shaken out centrifugally and joins the roughed-out coarse material discharging from spout *d*, while the cleaned fines leave by pipe *e*.

Flowsheets involving classifiers. Air classifiers normally make two products only, a coarse and a fine. If three sized products are wanted from one stream, it is necessary to use either two classifiers or a classifier and a screen. Several arrangements are shown in Fig. 41.

(±) Intermediate product.
(∓) Intermediate product different from (±).

Fig. 41. Flowsheets for air-classifier circuits.

Item A. This is the fundamental single-classifier flow, where a stream of mixed sizes is broken into a coarse (+) and fine (−) product.

Item B shows a screen-classifier combination, in which the coarsest material is scalped off by a screen and the screen undersize (comprising improved classifier feed) is split into an intermediate (±) and fine product by the classifier.

Item C is the inverse of item *B*, the classifier scalping out fines, and the screen separating the classifier oversize into a coarse and intermediate fraction. Its principal use is when screening is necessary for making two granular products, and fines in the feed blind the screen cloth.

Item D is a 3-classifier arrangement which serves to clean up the coarse and fine products, and gives two intermediate products having size distributions somewhat different from the usual run.

Item E illustrates an arrangement that can be used to produce an ultrafine product once through from a long-range feed.

Item F is similar to item *E* but involves handling much less air through the filter. Only 2 to 20% of the air is vented, according to the amount of moisture in the feed and the temperature of the air. For a given combined moisture content in the feed and new air, a higher temperature must be maintained in item *F* than in item *E*, but fuel consumption is not necessarily higher in *F*, since less heat is carried away in vented air.

Item G represents a closed grinding circuit, commonly used for unit firing with bituminous coal. The classifier *C* is combination-type with gravity roughing.

Item H is a closed grinding circuit using a mill without air sweeping, and mechanical means to deliver mill product to a combination-type centrifugal-roughing classifier. This flow delivers a nonaerated product in contradistinction to the flow of item *G*.

Item I is a variant of item *G* to the extent that a collector receives and de-aerates the classifier fines, and that collector gas is recirculated to the mill, less a small amount of vented gas, moisture, and ultrafine solid.

Item J is similar to item *G*, but differs in that the grinding mill is air-swept, conveyance is pneumatic but the coarser material does not pass through the fan, and the product is de-aerated.

Item K is the same as item *I* except that fines are scalped out of the mill feed by the feed classifier and combined with the product of the grinding-mill classifier. This is a useful arrangement with a feed already relatively fine, which tends to pack and cushion in the mill.

The differences in method of conveying, and, in pneumatic conveying, in the location of the fan, as shown in these flowsheets, may be important from the standpoint of space requirements and wear of fans, but do not affect classification materially.

Floating velocity. The air velocity required to float a particle when the current as a whole is vertically upward is usually different from that at which the particle settles in still air, and both are different from the velocity necessary to transport the particle when a major component of the current direction is horizontal, as in cyclone-type apparatus. (See Eqs. 6, 7, 14, 15.) Few data are available for either floating or conveying velocities for specific materials of definite sizes. Croft (*Thermodynamics, Fluid Flow and Heat Transmission*, McGraw-Hill Book Co., 1938) gives a few values from which the following are selected. ***Floating velocities,*** f.p.s.: COAL: 300-m., 0.5; 100-m., 3; 50-m., 10. COKE: 20-μ, 0.3; 150-μ, 2. SAND, FOUNDRY: 9; RIVER: 14. SPHERES, 62 lb. per cu. ft. struck volume: 0.79-in., 72; 0.36-in., 48. 125 lb. per cu. ft.: 0.79-in., 100; 0.36-in., 69; 187 lb. per cu. ft.: 0.79-in., 125; 0.36-in., 84. SPHALERITE: 0.08-in., 58.

Croft's velocities for conveying are of the same order as the lower ends of the ranges in Table 21. Martin's values for quartz of different sizes are given in Fig. 1. See also Table 1.

Temperature. Martin (*26 Cer S 21*) notes that the supporting power of gases increases with their temperatures; thus the diameter of particles supported at 1,000° F. was 1 1/2 times that of particles supported at 60° F. by a current of the same velocity.

12. COMMERCIAL CLASSIFIERS

Practically all modern air classifiers utilize both inertial and gravitational forces in a combination in which the relative strengths of the two kinds of forces are adjustable as part of the regular operation. The machines which are built and operated as separate units do the roughing by inertia, since inertial forces, engendered centrifugally, are much greater than gravitational (see Table 22), and consequently are more rapid, give a wider range of adjustment, and permit use of smaller apparatus. On the other hand, the majority of built-in classifiers utilize

gravitational roughing because such utilization is effected by simple increase in the intensity of air sweeping, and further because of mechanical difficulties in joining the grinding mill and a classifier of the centrifugal-roughing type in one apparatus.

Classifiers utilizing centrifugal roughing

These machines, ordinarily called MECHANICAL-AIR CLASSIFIERS, are illustrated in principle in Fig. 40, item *I*. The essential parts are: (*a*) a mechanical device for effecting the primary inertial differentiation, (*b*) a circulating fan and means for separate presentation of the two fractions roughed out in (*a*) to the fan stream for gravitational sorting, (*c*) an auxiliary inertial separator for a second working over of the finer fraction, and (*d*) draft regulators and deflectors for controlling the strength and direction of the air stream. The Gayco centrifugal, Raymond Whizzer, and Sturtevant Whirlwind classifiers are typical.

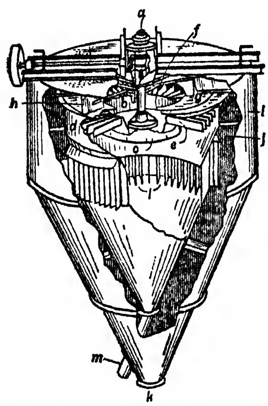

FIG. 42. Gayco centrifugal classifier.

Gayco centrifugal classifier (Fig. 42) is fed at *a* through a hollow shaft *b* which delivers to a whirling disk *c*, bolted to the shaft. Material is thrown from *c* by centrifugal force, and in the space between the rim of *c* and the wall of the inner cone *d* it encounters a rising current of air. The larger, heavier material, having the greater inertia, travels in a roughly horizontal direction until it meets the wall of the cone, where it is largely out of the air stream and can slide downward under the action of gravity. The material small and light enough to be lifted by the rising current travels upward with it and, with it, is thrown into a vortical whorl by the blade-type fan *e*, mounted as shown on shaft *b* above disk *c*. The coarser material in the rough fines is here thrown out by centrifugal inertial forces and falls down along the wall of inner cone *d* to join the coarse initially shaken out. The remaining fines travel on with the rising air stream through central opening *f* in horizontal shutter *g* into the feed zone of an upper fan with blades *h* mounted on arms carried on a hub on shaft *b* as shown. In this upper zone the fine material is largely thrown

to the wall of outer cylindro-cone *i* and travels down, assisted at first by the down-turned stream of air in the annulus *j*, until it reaches an outlet valve at *k*. The main stream of circulating air turns inward through vanes *l*, being denied egress at *k*, and then, being further denied egress at *m*, turns upward. The combined stream of primary and secondary coarse material, leaving the lower edge of cone *d*, falls across this inward upward air stream, and the fines are winnowed out and carried on upward as previously described, completing the circulating path. The cleaned coarse material falls down the walls of the inner cone and discharges through a suitable valve at *m*. The adjustments in this apparatus are the speed of shaft *b* and the opening *f* in the diaphragm damper *g*, the former controlling the inertial forces, the latter the gravitational.

Sizes, power requirements, and capacities, as rated by the manufacturer, are given in Table 23.

Raymond Whizzer classifier (Fig. 43) is like the Gayco in general construction and operation. It differs in details and in methods of adjustment. In the form shown (DOUBLE-WHIZZER TYPE) there are two whizzers or separator fans *a*, which serve to intensify the secondary inertial treatment of the fine material. The conical rims *b* surrounding the tips of the fan blades impart a downward component to that part of the coarser material that is thrown out in the planes of the fans. Whirl is controlled in the whizzer zone to a certain extent by the slide dampers *c*, controlled from outside the shell, a number being spaced around the inner-cone periphery directly above the fans. In the single-whizzer form the aperture below the circulating fan *f* is adjustable by means of sliding plates actuated by screws projecting through the housing.

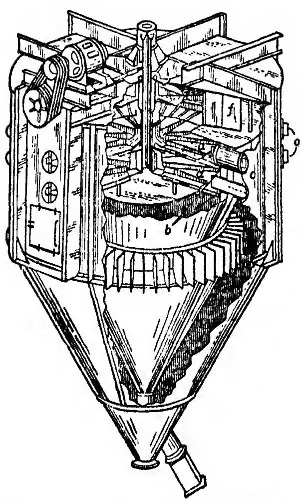

FIG. 43. Raymond Double-Whizzer classifier.

Catalogue data are given in Table 24.

Sturtevant Whirlwind classifier (Fig. 44) differs from the two machines of the same general type previously described in that the feed is introduced through a hopper *a* into a chute *b* surrounding the drive shaft, and that the vanes *c* are set at an angle to the radii. Adjustments are speed, radius of upper fan *d* (by moving the blades

on the arms), number of blades e on the lower fan, and area of top opening, which is varied by moving plates f by means of rods g. The nature of such adjustments has been discussed in connection with Figs. 42 and 43.

Sizes and power consumption may be approximated from Tables 23 and 24.

Hardinge Loop classifier (Fig. 45) is of the inertial-roughing type, but the inertial effect is generated by tangential introduction of feed through nozzle-shaped pipe q into the voluted horizontal semicylindrical chamber d. Damper k permits distribution of initial feed between the outer and inner volutes, and the position of that damper also controls the centrifugal effect, since the larger the fraction split into the inner space t, the lower the velocity in the outer volute. The counterflow through t from k may be increased to the point that inertial effects disappear. The coarser material concentrates in the air layer next to the walls d and l, due to the centrifugal action of the swirl. The coarsest material travels down over slide f and, at throat r, is met by a current of air rising through h, which winnows out fines and carries them up again into the inner volute for reworking. The intensity of this action is controlled by volume control at damper j and/or by cross-sectional area at r determined by moving f by screw g. Material suspended in the outer volute and falling from edge s of the inner volute, is subjected to a certain amount of gravitational settling in zone t. Centrifugal force being higher in the inner volute, the suspended material is robbed of further intermediate coarse material therein. The fine material, still suspended, leaves with the air through central outlet m and passes thence, through pipe n to collector o. Winnowed coarse material discharges through pipe u. The floated product is finer the larger the centrifugal effect.

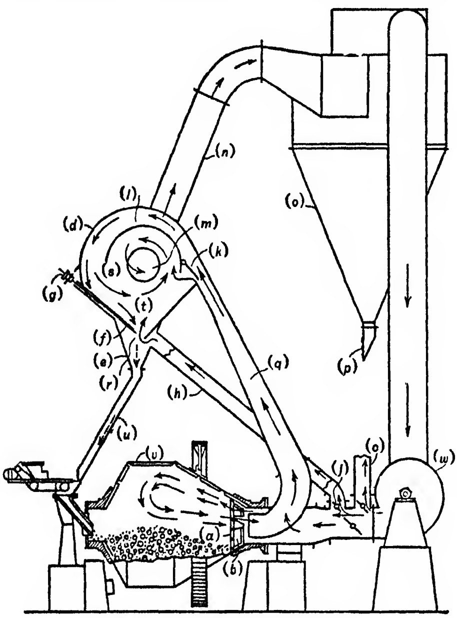

Fig. 45. Hardinge Loop classifier.

In the set-up shown, the classifier is operated in closed circuit with tumbling mill v. Circuit air blown in by fan w, which takes suction on collector o, sweeps the free space generally above the load in the mill, as indicated by the arrows (REVERSE-CURRENT CLASSIFICATION), and carries the finer material with it in suspension into feed pipe q. Trough-type lifters b, behind grates a, also pick up material discharged through the grates

in normal fashion (Sec. 6, Art. 3) and shower it across the outgoing stream. Air from the blower outlet is bled off through h as needed, via damper j, to supply the necessary rising current at r. Pipe c is a vent to relieve the system of moisture and excess air; make-up air comes in with the mill feed; the quantity is regulated by dampers at the fan discharge.

Catalogue data are given in Table 25.

Classifiers utilizing gravitational roughing

These classifiers are characteristically, although not necessarily, built integral with grinding mills, being set directly above the grinding zone.

Double-cone type (Fig. 46) comprises inner and outer cones e and d respectively, the inner hung in fixed position with respect to the outer, with communication between the two effected via shuttered openings b. In operation, the lower cone is mounted over a space in which solid is in semisuspension in air, as *e.g.*, the grinding zone of a medium-speed

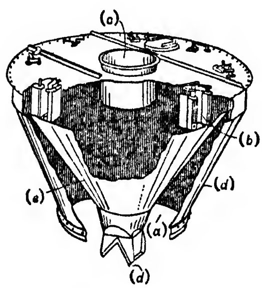

Fig. 46. Double-cone classifier.

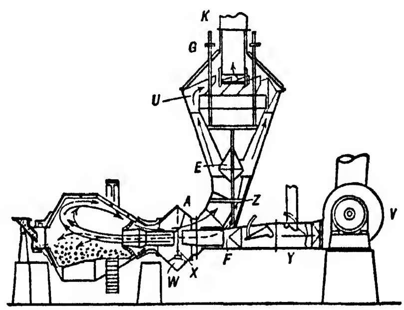

Fig. 47. Hardinge Superfine classifier.

fixed-path mill (Raymond, Williams, etc., Sec. 6, Art. 2), and forms the outlet for the air stream. This stream, carrying suspended solid, rises through annular space a, roughing out more or less of the coarsest material as it does so, and moves on upward to the top and thence through adjustable vanes b which are set at an angle so as to produce a cyclonic whorl in the inner cone. Here a second, inertial classifying action takes place, the heavier material being thrown to the walls of the inner cone and discharging through d back into the crushing zone, while suspended fines travel with the air stream through central top exit c to a collector, furnace, or the like.

Hardinge Superfine classifier (Fig. 47) is of the double-cone type, modified to permit reworking of the inertial granular product by gravitational winnowing before return to the grinding zone. As shown in the figure for use with a tumbling mill, classifier feed is swept from the mill by reversing air currents from blower V, and is subjected to a preliminary roughing in the revolving double-cone enlarged zone A, attached to the mill trunnion, wherein coarsest material is dropped out by reason of the velocity reduction. Oversize dropped in A is lifted by radial vanes W and showered across break X in air-inlet pipe Y and is carried back into the mill. The remaining material, in suspension, is conveyed through pipe Z to the bottom of the intercone space, dropping out further coarse material, which falls back into pipe Y at F and is swept thence back into the mill. The double-cone action is the same in principle as described above, but vanes U are stationary, and increase in angularity from bottom to top, while the inner cone is suspended and adjustable vertically through hand wheel G. Elevation of the inner cone has two effects: (a) it increases the cross-section of the intercone space, thus decreasing rising velocity and dropping out finer material; (b) it raises the point of inflow of air to the spiral vanes U, thus effecting a more tangential introduction at higher velocity, so that finer material is thrown out in the inner cone, the result being a finer discharge through pipe K. Double cone E, which moves with the inner cone, produces a Venturi effect, which aids efflux of the cone discharge; the solid, dropping off the periphery of this cone, is given a final gravitational working by the incoming air stream. A sliding seal between A and the lower end of Z makes junction between rotating and stationary parts of the system.

Sizes are from 1-ft. to 12-ft. diameter, power consumption correspondingly from a fraction to 125 hp., and capacities from a few pounds to 50 tons per hr. of finished product.

Mechanical type of gravitational-inertial classifier is shown in Fig. 48. As pictured, it is working in conjunction with a hammer mill *h*, fed at *i*, and air-swept by recycled air entering at *a*, and leaving via suction pipe *f* of circulating fan *g*. Gravitational roughing takes place in chamber *b*, where the coarsest material settles out of the rising current.

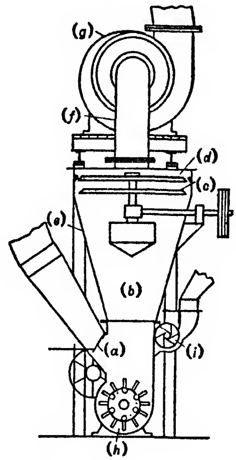

FIG. 48. Mechanical type of gravitational-inertial classifier.

Centrifugal classification drops out further granular material in the whirling zone set up by the thin-bladed fans *c* and *d*, the material dropped out returning to the crushing zone down the walls of the steep-sided cone *e*. Discharge is to a separator whence denuded air comes back to *a*. Fans *c* and *d* are driven by a variable-speed motor, thus controlling precipitation.

Fan speed. The effect of speed variation on product is shown in Fig. 49. The relation between fineness of product and capacity is shown in Fig. 50.

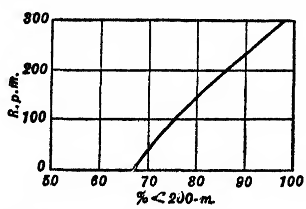

FIG. 49. Effect of classifier-fan speed on fineness of product.

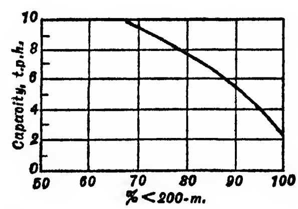

FIG. 50. Relation between fineness of air-classifier product and classifier capacity.

SECTION 10

WASHING AND SCRUBBING

Scrubbing and washing are the counterparts of crushing and concentration respectively, as applied to the treatment of crudes which are geologic residuals. Such crudes normally comprise rock that is more or less unconsolidated, in which the important mineral species differ markedly in grain size and bulk hardness. Particle size alone is ordinarily, but not necessarily, the property upon which separation is based. Water is the usual separating medium, but air is sometimes used. The names carry over from parallel familiar household activities and imply the same actions, *viz.*, soaking, rubbing, pounding, agitation, spraying, and the like in the presence of water, and removal of the water from the larger solid, carrying the smaller solid in suspension. By these means clay is washed from harder and more coarsely crystalline minerals and rocks generally; sand from aggregate, fine sand from coarse sand, loam from fine sand; sand from shell; decomposed blue-ground from diamondiferous sand and gravel; silica sand from lump hematite, phosphate, barite and the like; and slimy limonite from associated granular material.

SCRUBBING

Definition. Scrubbing is disintegration effected by forces which are relatively light, judged by ordinary standards of comminution, but are sufficient to break down soft unconsolidated material such as clay, or to sever the bonding brought about between grains by precipitates of salts and the like. Scrubbing is usually effected by rubbing the larger and harder grains together, as by tumbling the mass, but in some cases the force of a water jet playing against a mass of crude backed by a rigid surface is sufficient. Scrubbing normally precedes washing, but the two may proceed simultaneously.

1. PRINCIPLES OF SCRUBBING

The materials to be scrubbed, the form and character of the material to be removed by the scrubbing, and the results demanded determine the method and apparatus to be employed. If, as in the preparation of lump limestone for burning in shaft kilns, the finished material is the lump stone and the impurity to be washed away is adhering clay picked up in quarrying, the method indicated is one in which the lumps of relatively hard stone are rubbed against each other in the presence of water; the degree of tumbling required depends upon the resistance of the clay to disintegration and upon the purity demanded. If the clay is tough, adhesive, and water resistant, and if standards of purity are high, the stone must be tumbled until most of the surface concavities are eliminated, since only thus can such clay be removed. On the other hand, the clay bonding in many so-called cemented gravels containing well-rounded smooth boulders may be removed by even such light rubbing as is involved in passage through chutes and over vibrating screens, particularly if subjected to vigorous sprays. In general the smaller the fragments to be scrubbed the more irregular their surfaces, and the softer they are the more difficult it is to scrub them.

Materials subjected to scrubbing may be classified on the basis of the form of the soft component, since this determines the method of scrubbing. **Nodular materials** are those in which the harder grains, ranging in size from very small to massive, are

scattered through a matrix of clay or clay-bound sand. The important characteristic of this type of material from the standpoint of scrubbing is that the material to be disintegrated is massive and frequently tends to form rounded lumps (CLAY BALLS) which are highly resistant to disintegration. CEMENTED MATERIALS are those in which the harder particles predominate, but in which there is sufficient intergranular cementing material to form a substantially continuous interstitial filling; cemented gold gravels and some tin gravels are typical. COATED MATERIALS are usually fine grained, relatively unconsolidated, but coated, and, perhaps, lightly cemented, by films of decomposition products, precipitates such as iron oxides, and the like.

Methods of scrubbing are (1) jet-impact, (2) tumbling, (3) stirring. Each may, sometimes advantageously, be preceded by soaking. Additionally, in difficult cases, modifications of standard methods of crushing and/or grinding are employed.

2. JET SCRUBBING

Jet-impact scrubbing is used for primary disintegration of both nodular and cemented crudes, and in final scrubbing of gravelly aggregates and, less frequently, of sands. The underlying principle is subjection of the solid to the mechanical impulse of the jet, at the same time supporting it against a rigid or semi-rigid backing so as to utilize as much of the jet energy as possible in setting up internal stresses in the lump, rather than in effecting transport. The size and velocity of the jet to be employed depend upon the size of the material and the method of backing. If the lumps move as a mass under the impulse of the jet, energy is being wasted. If the material being jetted is submerged, so that a part of the force of the jet is expended in moving the submerging water, energy is again wasted. If the material is moving toward the jet as it is struck thereby, the force of the impact is increased. It follows that jet scrubbing is most effective when material is held in place, as in a gravel bank sufficiently steep to permit rapid runoff of water, or when it is moving down a steep chute (again permitting rapid runoff), or is supported on (and preferably moving toward the jet over) a rigid perforate surface.

Hydraulicking is employed in mining many nodular crudes and cemented gravels and sands, not only because such excavation and transport are relatively cheap, but also because the full impact of powerful jets can thus and only thus be brought to bear on the finer sands. For methods and costs of hydraulic mining see *Peele;* for sluicing see Sec. 11, Art. 26.

Monitors are nozzles, usually 1-in. diameter or larger, supplied with water at pressures of 50 to 150 lb. per sq. in. and upward. They are used in the plant on lump crudes of nodular or cemented character, the crudes normally being supported on a grizzly sloping toward the nozzle stand. A typical simple arrangement is shown in Fig. 1 (*21 IMM 230*).

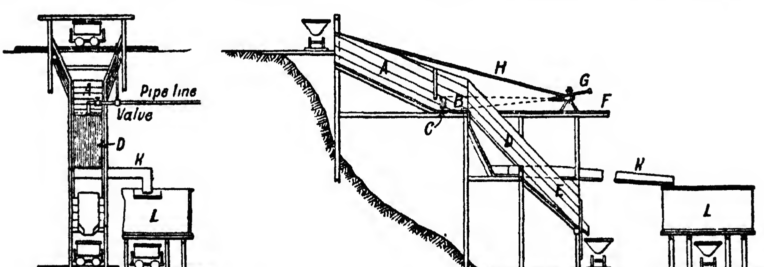

FIG. 1. Monitor washing plant.

The ore was delivered on an upper track, dumped into a chute *A* and brought to a washing platform *B*, where it was disintegrated by means of a stream from a nozzle *G*. Disintegrated material flowed over a grizzly *D*, washed oversize was collected in a bin *E*, and undersize flowed through launder *K* to a settling tank *L*. See also Sec. 2, Fig. 135.

At CHARLESTON MINING Co., Mt. Pleasant, Tenn. (*44 #9 RP 37*), clayey muck from steam-shovel mining is disintegrated on a grizzly with 110-lb. water from hydraulic guns, adding 1,500 g.p.m. (for 125 t.p.h. of solid); grizzly undersize then passes to an 8×25-ft. blade mill and thence to $^3/_{16}$-in. Low-head screens.

A modification of monitor scrubbing was used at MONROE SAND & GRAVEL Co., Monroe, La. (*41 #9 RP 46*). A cemented gravel containing about 20% clay was excavated by steam shovel and transported by side-dump cars to the shore of a lake, where it was dumped. A header with a plurality of

jets under 25-lb. pressure was carried along above the dump, and the dump was washed into the lake by the jets. The material was then picked up by a suction dredge and washed and sized in the usual fashion (Sec. 3, Art. 38). The lake served both for storage and to soften and disintegrate small lumps of clay by soaking.

Water consumption for jet scrubbing is substantially impossible to estimate. A 1 1/2- or 2-in. monitor under 60- to 100-lb. pressure will effect rough disintegration of a relatively large tonnage of material per hr., sufficient to permit passage through a 1 1/2- or 2-in. grizzly, and the water therefor is readily calculable, *e.g.*, for a 2-in. nozzle at 100-lb., 1,100 to 1,200 g.p.m. is required. Thus if extensive monitor scrubbing is contemplated, a large supply of cheap water is necessary.

Jet scrubbing on screens. See Art. 6.

3. TUMBLING SCRUBBERS

Tumbling scrubbers are rotatable cylindrical shells, set more or less horizontally, with end closures sufficient to maintain a body of liquid within them, and with internal projections that serve to tumble the load on rotation. They operate, usually, at speeds well below critical (Sec. 5, Art. 2) and thus depend for their scrubbing action primarily on rubbing between the lumps of hard material in the feed, supplemented by such impact as occurs in cascading (see Sec. 5, Art. 2). At the usual low speeds the forces are insufficient to break material as soft as the ordinary pebble phosphates, but may disintegrate barite (Sec. 3, Art. 3) or nodular manganese oxides. Ordinary clays disintegrate relatively completely, if the harder material is 2-in. lump or larger, and the pulp is kept thin; tough clays, small lump, and thick pulps all tend toward the production of clay balls, which tend to float through without disintegration. The remedies are higher speeds to cause definite cataracting, introduction of a light load of steel tumbling media, and thin pulp; one or more being applied according to circumstances.

Drum scrubber in its simplest form (Fig. 2) is a cylindrical welded-steel shell, 5 to 7 ft. diameter by 8 to 25 ft. long, with plane or conical ends. It is mounted, with axis horizontal, on tires and rollers, and revolved 10 or 12 r.p.m. (170 to 190 f.p.m. peripheral speed) by spur gear. It is lined with chilled cast-iron or manganese-steel blocks, usually in alternate courses of smooth and lifter types, the lifters being set at an angle so as to both elevate and convey settled material from feed to discharge end. Water and suspended fines flow through, either concurrent or countercurrent, by reason of difference in diameter of feed and discharge openings. Lifters of spiral or radial types on the discharge head *a* may be used to lift the scrubbed rock to the discharge opening (see Sec. 5, Art. 8). Weight complete is from 20,000 to 85,000 lb. over the size range 5×8- to 7×24-ft.

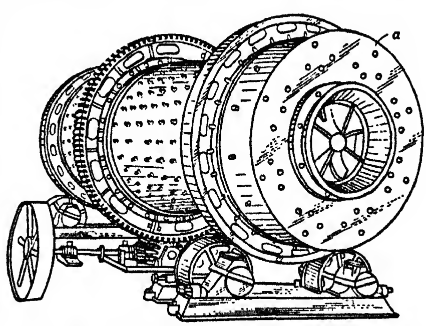

FIG. 2. Drum scrubber (*after Allis-Chalmers Mfg. Co.*).

Operating conditions. FEED SIZE for standard construction is usually 4-in. limiting. Larger lumps, 6- to 10-in., require larger feed and discharge openings and redesigned discharge-head lifters. CAPACITY is a matter of conveying rate, which depends upon the projection and inclination of the lifters and upon the coarseness of the feed. Manufacturers' ratings for 5-ft. drums are 20 to 75 t.p.h., for 6-ft. from 75 to 125 t.p.h., and for 7-ft. from 200 to 300 t.p.h., the lower values at each size corresponding, of course, to the higher and tougher clay contents of the feeds. POWER CONSUMPTION varies with the amount and specific gravity of coarse material in the feed, and upon the hardness of the sand and its resulting tendency to lift the load. Motor sizes recommended range from 10-hp. for a 5×8-ft. drum to 40-hp. for a 6×20-ft. and 125 hp. for the 7×24-ft. size. WATER CONSUMPTION depends upon the service, but is roughly within the range of 1 to 4 tons per ton of solid feed.

Blade mill; paddle mill (Fig. 3) is essentially a drum-type conflow scrubber with log-washer teeth *a* of adjustable angularity (Art. 4) and without an inside wash spray. In one form, it is trunnion-mounted, with trunnions capable of passing 12-in. lumps, and is fitted with a large gravity-feed hopper, a lifter-type discharge for coarse material, and a trunnion drum (see Fig. 4) having annular retaining rings to aid in maintaining level with a surging feed. It is built in the belief that the higher blades (as compared with the simple drum-type scrubber) will be more effective in disintegrating clay balls, by reason

of a cutting action; and that control of time-factor may be effected by adjustment of the pitch of the blades. Sizes are 6- and 7-ft. diameter by 16- to 30-ft. length. Performance data are not available but makers' ratings are 200 to 300 t.p.h.

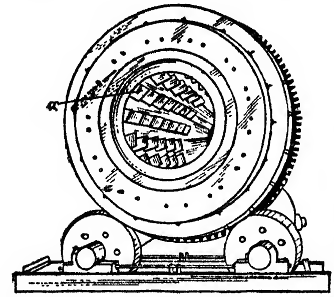

FIG. 3. Blade mill (*after McLanahan & Stone Corp.*)

Cone-ended scrubber is a cylinder with 30° conical ends and spiral lifters carried up into the discharge-end cone to aid in discharging coarse material. It is effective for easy scrubbing, such as for lump limestone; it is doubtful whether it would be effective for difficult work.

Super-scrubber is used for refractory feeds that require intense tumbling for disintegration. LIFTERS are given more projection and the inclination toward the discharge end is decreased or eliminated. SPEED is increased to between 80 and 90% of critical so that there is much cataracting of the charge. POWER requirement is thus more than doubled. CAPACITY is decreased by reason of the decrease in conveying thrust. More good rock is crushed and broken. The machine should be heavier and more rugged generally to withstand the heavier duty.

Counterflow scrubber is designed to remove clay and fine sand from gravel and stone during the scrubbing operation. One form is shown in Fig. 4. It comprises a cylindrical shell with dished ends, trunnion mounted, with cylindrical axis horizontal. The feed end is lined with spiral lifters *a* directed toward the discharge end, so that material is heaped up beyond the inner ends of the lifters and thereafter flows by gravity to and through the discharge trunnion. The remainder of the cylinder is lined with lifter liners *b*, the ridges *c* parallel to the shell axis. A grate *d* at the feed end forms a perforate annulus around the feed chute, holding back the coarser material, but permitting egress of fines. Liquid flow toward this end is induced by making the diameter of the discharge opening smaller than the outside diameter of the grate and feed-trunnion opening. Spray pipe *e* with deflector jets (Fig. 9) projects into the discharge end as indicated. Speed is such that, with the lifters, the load is largely cataracted, and the low-level discharge minimizes cushioning. Counterflow acts to decrease in-load cushioning by removing much fine material shortly after entry; it also does final washing of product with the cleanest water. Usual diameters are 5 to 7 ft. and lengths from 1- to 1 3/4-times diameter. Outside screen (TRUNNION TROMMEL) *f*, bolted to the discharge spout, is used when close sizing of coarse products is unnecessary.

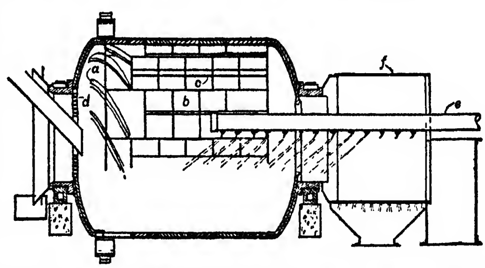

FIG. 4. Counterflow scrubber (*after Allis-Chalmers Mfg. Co.*).

In another form, with plane instead of dished ends, a chute projects adjustably into the discharge opening and the lifters are carried to the end of the shell; the combination serves to elevate and drop scrubbed material into the chute, and the extent of washing may be varied by the inward projection of the latter.

Screen scrubber is an imperforate section, usually at the head of a revolving screen washer (Art. 6). The cover sections are steel plate or manganese-steel castings, usually unlined, with longitudinal lifters, and, normally, an annular baffle at the end to increase time-factor somewhat and to make the falling load slightly heavier than otherwise. The action of a screen scrubber is much lighter than that of the drum-type machines above described; correspondingly, less thorough disintegration is demanded. For further detail of construction and operation see Sec. 7, Art. 5.

4. STIRRING SCRUBBERS

Stirring scrubbers are essentially stirring devices in which thick pulps, ordinarily too fine or too soft to be scrubbed effectively by tumbling, are treated. Some of them, such as the pug mills and mulchers, depend upon moving blades to actually cut through soft

clay lumps; the majority, however, attempt by thorough stirring to produce repeated rubbing together of hard-particle surfaces in order to rub off adherent films of softer materials.

Pug mill (Fig. 5) consists of a horizontal trough *a* in which is mounted a shaft or shafts *b* carrying blades *c*, usually set at a sufficient angle to the shaft to impart to the pulp some longitudinal movement. Diameter of blade-tip circle ranges from 16 in. to 3 ft. according to the duty. Speed ranges from 10 to 50 r.p.m. The apparatus is used for soft clays containing relatively small amounts of small granular materials. CAPACITY depends upon the amount of disintegration necessary and the difficulty in effecting it; each case is more or less special, and can be decided only on the basis of test and experience. Form C, Fig. 5, represents a mixer in a revolving barrel and is used when the charge tends to be sticky and not travel through the normal type of mill.

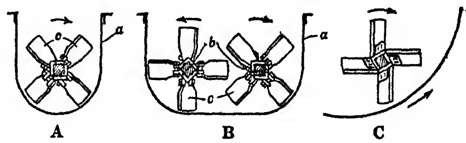

FIG. 5. Pug mills.

Log Washer

A log washer has two functions, *viz.*, (*a*) to disintegrate clay and clay-bound sand matrices, and (*b*) to separate disintegrated fines from lump material. Both disintegration and transport of the coarser material are performed by blade-bearing inclined revolving LOGS, which agitate and turn over the feed in water in a box and at the same time push the settled lump material up an inclined bottom by reason of the spiral positioning of the blades. Discharge of fines is effected by overflow, in suspension in water, at the lower end of the box.

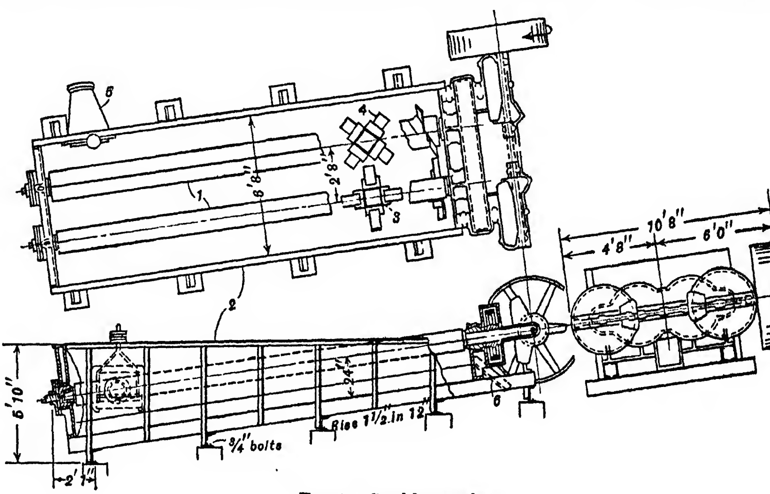

FIG. 6. Steel-log washer.

Description. Log washers (Fig. 6) comprise essentially one or two heavy inclined members or logs (*1*) mounted rotatably on a slope of 0 to 2 $^1/_2$ or 3 i.p.f. in a rectangular or round-bottomed trough (*2*), with bottom on the same slope. Logs were made originally (and still are in small, crude plants) of 12- to 18-in. sticks, shod full length with iron straps, and fitted with chilled-iron gudgeons (Fig. 7), the lower gudgeon or both gudgeons passing through a stuffing box and carried in a thrust bearing. In modern forms the bearings are outside, roller-type, and the lower (drive) end of the shaft passes through a water-sealed stuffing box. In the modern apparatus figured, the logs are made of $8 \times 8 \times {}^3/_4$-in. angles welded to form an 8×8-in. box girder. Base plates (*3*) for holding reversible alloy-steel blades (*4*) are welded to the logs in such spacing (about 4 per ft.) and

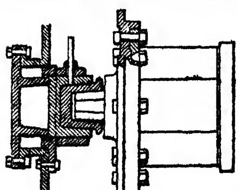

FIG. 7. Gudgeon, chilled-iron thimble and step bearing for wooden log.

position that the blades form an interrupted spiral with a pitch angle of 65 to 70° and a diameter of 20 to 40 in. Logs are made in 20- to 35-ft. lengths; in 2-log machines rotation is in opposite directions, rising in the center. Boxes are normally of steel, but often of wood, with adjustable overflow (*5*) and sand-discharge spout (*6*). Clearance between blade-tip circle and box bottom should be greater than the largest lump of feed. The upper 8 to 10 ft. of the box is usually sprayed. Normal speed range is 140 to 190 f.p.m. peripheral, the higher figure corresponding to the greater blade-tip circle; speeds up to 240 f.p.m. are shown in Table 1.

Table 1. Performances of 2-log washers on stone and gravel (*After Amos and Patterson*)

a Cost (1935), 4.6¢ per ton of washed product, of which power was 65%. Labor, 1 man to 2 machines.
b Foreign material, red clay in balls and coating the stone.
c Washed product.
d Refuse from hand loading at quarry face; includes loam and clay balls 1 to 6 in. diam.; also some clay-smeared larger rock.
e Easier washing than material in first line of table because clay had somewhat weathered. Repairs and maintenance, 0.17¢ per ton of feed.
f Cemented. Owing to increasing cementation a rotary washing screen with scrubber section would no longer clean the product sufficiently.
g Through 2-in. ring, on 1/4-in. vibrating screen.
h Slope, 1 i.p.f.
i Estimated.
k Minimum operable with this feed. Supply limited.
l Cemented.
m Pit run.
n Repairs estimated at 1 to 2¢ per ton of finished product.
o Clay-coated.
p 400 g.p.m.
q <1/4-in. removed by vibrating screens.

Turbo washers are log washers with perforated false bottoms through which water is forced under pressure. They wash the lump material more thoroughly than the ordinary log washer does.

Operation. LENGTH of machine affects time that material is subjected to the action of the logs and therefore the extent of disintegration and cleaning of sand, but it does not affect rate of sand movement and, therefore, has no effect on capacity. SLOPE affects the run-back rate from the sands; the steeper the slope the better the cleaning, all other things being equal. Within small limits, also, slope affects rate of sand travel and thus controls capacity. SPEED affects the force of the blade blows and thereby the disintegration; higher speed, however, increases transport rate and correspondingly decreases time-factor; usual range is 20 to 25 r.p.m. for the larger machines. Slow speeds must be used for difficult washing. WATER CONSUMPTION varies according to the amount of solid to be carried over; figures range from 1 to 8 tons per ton of feed. The larger quantities are required with sandy and loamy material; with stiff clay thicker pulp aids disintegration, and when coarse material is to be overflowed a thick pulp is necessary for buoyancy. Unless draining is necessary, spray water should be added as near the upper end as possible, at pressures of 20 or 30 lb. or more. Extra water added to increase volume of overflow should be introduced in the corners at the discharge end in order to give a counterflow effect. POWER required is from 15 hp. for a small single-log machine to 100 hp. for a large double-log machine; the requirement is generally lower the higher the clay content; consumption figures as low as 0.5 hp.-hr. per ton are reported. FEED is introduced on the upcoming side of a single log or between double logs and, in order to save power and wear, as near the head end as will produce a clean product. When the feed varies widely in amount of dirt, it should be brought in high enough above the washer to permit the actual feed point to be changed with the duty demanded. Maximum size of feed is usually about 3-in., but 4-in. stone can be handled in large logs. Large rock tends to work down-slope and jam in the lower end of the box; this can be prevented by feeding over a grizzly, with oversize delivered farthest up-slope.

Concentrating action in a log washer. Apart from the classifying action, which is simply a rough sizing, a log washer forms a stirred bed in which reverse classification, aided by the lifting action of the paddles, keeps the coarser material at the top, where it is most readily transferred up-slope. If the feed is a mixture of minerals of different specific gravities, the coarse particles of lower gravity simply float on the bed. The coarse particles of higher gravity are prevented from sinking in it by the stirring. The finer material not in suspension, which percolates, stratifies according to specific gravity; a part of the lighter can then be forced to overflow, while the heavier bottom material is carried up-slope by the conveying action of the logs. If the log is overfed, both scrubbing and washing decrease markedly; if the pulp is too thick, fine light material is carried into a heavy-mineral log product.

Capacity. Maximum capacity is determined by the transport ability of the logs acting as a blade conveyor. Manufacturers' ratings of this capacity at blade-tip speeds of 200 to 225 f.p.m. range from 50 to 80 t.p.h. for a 36-in. tip circle on material of 2.7 sp. gr. Performance figures are in this range. Maximum capacities for smaller sizes may be estimated from these on the proportion of the squares of the diameters of the tip circles. Total capacity is the raking capacity plus the discard. When washing is difficult, speed must be reduced; then reduce estimated raking capacity proportionately. For material of high specific gravity, increase tonnage estimates proportionately. An oversize allowance of 25 to 50% should be made to take care of surges.

Performance. At the Coleraine plant of OLIVER IRON MIN. Co., washing hematite ore at <2-in. ring, 36-in.×25-ft. turbo-type double-log washers at 14 r.p.m. received 160 t.p.h. each and made 40 tons of concentrate. Overflow was sent at the rate of 107 t.p.h. each to 20-in.×18-ft. 2-log turbo machines at 9 r.p.m., which made 32 tons each of concentrate. Both concentrates averaged 58% Fe and 10% SiO_2. In Alabama (*108 P 458*) log washers are used to wash clay and gravel from nodular limonite. Usual capacity of 36-in. 2-log machines, 20 to 30 ft. long, at 12 to 15 r.p.m. is 50 to 75 t.p.h. with 8 to 25% of the feed being raked up as concentrate carrying 40 to 45% Fe. Maximum size of feed is about 3-in. Treating manganese ores (*Bul 734 USGS 99*) a double 25-ft. log making 12 to 15 r.p.m. treated 40 to 50 tons per 24 hr. with a water consumption of 50 to 75 g.p.m. and 20 to 25 hp.

Performances at a number of installations washing limestones and gravels are given in Table 1 (*129 A 145*). For use in mills see Secs. 2 and 3.

Character of products. Log washers are largely sizers so far as the coarse product is concerned and this must usually, therefore, be further concentrated. The ordinary means are picking, jigging, or sink-float separation. There is some differential settling of fine material, but overflow cannot be considered finished tailing except for low-cost mineral, or for one not further concentratable.

Screw washer (Fig. 8) is a modification of the log washer designed for light scrubbing and washing of coarser sand. It comprises an inclined tank with sides built up at the lower end to accommodate a pool, the depth of which is controlled by means of an adjustable overflow weir at *a*. The screws *b*, usually 16 to 20 in. diameter, are cast or sheet-steel spirals carried in bearings outside the tank. Provision for thrust is made in the lower bearings, and the stuffing box at the lower end is water-sealed. Usual speed range is 20±5 r.p.m., and should be an operating adjustment. Feed is introduced into the pool at a limiting size usually $^3/_8$- to $^1/_2$-in.; the location of the feed point is nearer the high end the coarser the feed. Spray water is introduced on the upcoming side of a single spiral, or between oppositely rotating double screws near the high end, the location of the topmost jet being a compromise between requirements for cleanliness and dryness of sand. LENGTH is usually 15 to 20 ft. PITCH is 3 $^1/_2$ to 4 $^1/_2$ i.p.f., usually increasing with length. CAPACITY ranges from about 10 t.p.h. for a 16-in. single screw doing difficult cleaning and making a relatively dry sand to 70 t.p.h. when making an easy separation in a 20-in. 2-screw machine. Double-screw capacity for a given speed is substantially twice that for a single screw; capacity is directly proportional to speed and to the square of the diameter of spiral. Provision may be made to introduce bottom water near the shallow end of the pool; this tends to make a cleaner sand.

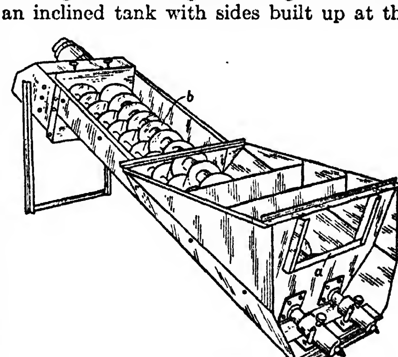

FIG. 8. Double-screw sand washer.

Modified log washer for sand washing, used at P. J. WEISEL, INC., Corona, Calif. (*41 #8 RP 55*) in production of glass sand, had alternate radial and 45° blades, 13 $^1/_2$-in. radius, mounted on a 1 $^{15}/_{16}$-in. shaft in a horizontal tank. The squeezing effected by the radial blades is reported to have been effective in disintegrating small clay balls (see Sec. 3, Fig. 64).

5. SAND SCRUBBING

Sand scrubbing is essentially removal of films or coatings, *i.e.*, disintegration of clay masses or the like is normally not involved. The method employed depends upon the refractoriness of the coating.

Scuffing is a name recently applied to a form of scrubbing, the object of which is, in general, to remove fine-grained crumbly or particulate incrustations from sandy materials. Thus clay and fine phosphate slimes are removed from pebble-phosphate particles prior to oiling for table flotation (Sec. 12, Art. 30; Sec. 3, Figs. 51, 54); decomposed feldspathic material is removed in preparing spodumene for froth flotation (Sec. 12, Art. 53); and fine powdery hematite is rubbed from quartz grains in treatment of the oölitic hematites of the southern U. S.

The methods employed for scuffing depend upon the difficulty of the job. Tumbling mills (Sec. 5) with light loads of rods or balls are used in phosphate and hematite treatment; chaser mills are used for some glass sands, tumbling mills with a load of slugs for others (*43 #1 RP 104*); vigorous stirring in a thick pulp in a beater box such as the agitation compartment of an agitation-froth machine (Sec. 12, Art. 27), with a dispersant present to prevent redeposition (Sec. 12, Art. 7) is sufficient in other cases.

Separation in scrubbing is never clean. When cleanliness is desired the scrubbed material must be subjected to some further form of washing or other method of concentration.

WASHING

Washing is, properly, separation on a size basis between particles differing so widely in size that the smaller are readily suspended in a fluid current which fails completely to suspend the larger. The term is applied also, however, to classification, particularly in the sand and gravel industries and in those concentrating operations in which the crude separations possible in classifiers are sufficient, *e.g.*, for certain iron ores, manganese ores, phosphates, and the like.

Washing usually involves more or less scrubbing. This is particularly true with crudes which require light scrubbing only, such as crushed stone, dredged shell, and many sands and gravels.

The principal apparatus used for washing are screens for sizes coarser than $^1/_8$-in.; sand tanks, mechanical classifiers and hindered-settling hydraulic classifiers for separations in the range from 10- to 100-m.; and hydro-bowls and air classifiers in the finest range.

6. SCREENING WASHERS

A washing screen is an ordinary screen provided with more or less powerful water jets playing on the oversize material, suitably housed to lead away liquid undersize and confine splash.

Rotary washing screens are used when a considerable amount of disintegration, usually of clayey material, is necessary, when tumbling and some resultant breakage of oversize are not harmful, and when separation is to be made at sizes not finer than $^1/_8$-in.

The greatest development of rotary washing screens has been in connection with gold and tin dredging. In this service single-jacket screens up to 9 ft. in diameter and 50 ft. long, usually with a scrubbing section, have been built. See Sec. 2, Art. 20, for details of construction and operation in gold and tin dredging. See Sec. 7, Art. 5, for the forms ordinarily used in treating industrial minerals. Such screens when used for washing differ from those used for screening alone in the fact that they are normally equipped with lifters, they have internal sprays, and may have retarding rings to thicken the bed and thus cause a certain amount of in-load rubbing.

Rotary screens without lifters have been widely used for light washing and sizing crushed stone and gravel. They have been largely displaced, however, by vibrating screens in most modern installations of this type, particularly when but little disintegration is required, or where heavy scrubbing is done separately (Art. 1). The only sacrifice in such substitution is loss of the transport and distribution to bins effected by the usual rotary. This loss is more than compensated for by the smaller weight, greater compactness, and higher capacity and efficiency of the vibrating type.

Rotary screens are pre-eminent in washing dredged shell. In this service there is considerable marl to be dislodged from the shell cavities and tumbling is essential to present both faces of the shell repeatedly to the washing jets. The accompanying sand

is fine so that screening, even at somewhat under $^1/_8$-in. on the outer jacket, is easy, and the shell is a cheap enough commodity to make it unnecessary to reduce aperture to effect the highest possible shell recovery.

Chains of heavy rod, hung in loops from the lifters, have been proposed for material that requires considerable scrubbing, and is deficient in coarse heavy lumps. The chains are to be hung in the scrubbing and/or coarse-screening sections. It is difficult to see how they could aid; any slap that they might exert would be on the downcoming side, which carries no bed; on the upcoming side the tendency would be to swing out and dislodge material from the lifter shelves at a lower elevation than otherwise, thus decreasing impact.

Capacity depends upon the requirements as to cleanliness of oversize, the size at which separation is made, and the amount of near-mesh material present. For broken rock and not more than 50% of oversize to any given screening surface, a base rate of 1 ton per 24 hr. per sq. ft. of screen surface per mm. of aperture is safe; this rate may be increased 100 to 200% in the case of the finer apertures ($^3/_8$- to $^1/_8$-in.) owing to the presence of plentiful wash water. For loose free-running and generally rounded gravel of long uniform range, add 20 to 25%. For bulky, irregular materials such as shell, apply a factor proportional to the decrease in bulk weight, and a further multiplier which may be 0.25 or smaller for blinding tendency. If considerable proportions of near-mesh material are present, apply a half-size factor H of the general order of magnitude given in Sec. 7, Art. 9. If high washing efficiency is necessary, a final efficiency factor, depending on the roughness and fines-holding nature of the surface and the adhesive character of the fine material, must be applied; this will be a divisor, the magnitude of which may be as great as 10, if, as in the case of oyster shell for making high-purity lime, the surface has recessed roughness and if the shell has been dug from a deposit containing considerable clay.

Shaking-screen washers have been installed on a few dredges (Sec. 2, Art. 21). They have been extensively used in washing pebble phosphate, and, following this practice, have been employed in treatment of similar ores such as barite and manganese. They have also been used as the exclusive means for screen washing of anthracite.

The philosophy underlying the use of the shaker in phosphate washing was that separation had to be made at a fine mesh, disintegration had already been effected in log washers (Art. 4), the shaker was as efficient as the trommel, had much higher capacity per square foot of floor space and of fine-screen surface, and was cheaper to install. The modern trend is toward vibrating screens, which actually have most of the advantages attributed to the shakers.

Sprays for phosphate washing are reported to have been most effective with 50-lb. pressure; light loads on the screens are essential for good washing.

Washing of anthracite on shaking screens is, except for the bull screen, entirely secondary to sizing; the screens were and are selected for this latter service because they cause the least breakage of any screen available.

For construction and operation of shaking screens see Sec. 7, Art. 6.

Vibrating screens are used for most modern sizing and washing of rock, gravel, and the like down to $^1/_8$-in. sizes when the scrubbing requirements are light. The types of screen which can run on low slopes are preferable if scrubbing must be done, and, in general, the cleaner the oversize product required, the flatter the screen chosen. The screens should be operated so as to produce a relatively thin bed and high activity of oversize, since turning of oversize for subjection of all sides to water is desirable.

Capacities may be reckoned on the basic rates given in Sec. 7, Art. 9, with the additional factors discussed under ***Rotary washing screens*** (*ante*).

Wash sprays. Various forms of spray nozzles have been devised to produce effective jets and spray streams. Two forms are shown in Fig. 9. Item *a* clamps to the header so as to hood a drilled orifice therein, the deflector being shaped to produce the form of jet desired. Item *b* is welded or clamped in position. The inner surface of the deflectors is polished in all cases to eliminate undirected spray. Spray water should be applied under at least 25-lb. pressure. The headers are run above the screen box, transversely to the flow; they should be close enough to the bed of material to impinge as sheets rather than as spray, and should be so spaced as to form a continuous sheet of water across the screen box at the level of the upper surface of the bed. The number of cross headers depends upon the amount of washing required; spacing is sometimes as close as 6 or 8 in. between headers. Spray pipes should be assembled, if possible, so that the entire assembly can be lifted to permit screen change.

FIG. 9. Spray nozzles.

Vibrating scrubber (Fig. 10) is a modified eccentric-drive vibrating screen with the screen box rebuilt to form two separate transverse deep pockets *a* with hoppered screen bottoms. Fishtail sprays are provided above each pocket. Independent feed streams are brought to each trough at the back side of the screen box in the figure, and the scrubbed material discharges through the screen-box wall at the front. The device is effective, at any economic capacity, only when the amount of scrubbing necessary is very small, since the superincumbent load is light and turnover is slight, if any, and almost wholly undirected and accidental, while the spray is effective on the particles in the upper layer only.

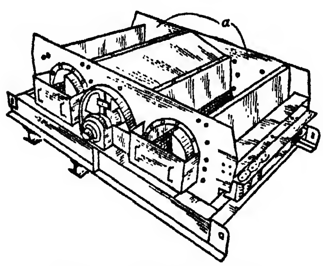

Fig. 10. Niagara scrubber.

A. E. Reed (*PC*) reports that 2 @ 2×6-ft. scrubbers handle up to 90 t.p.h. each of 7/16~1/8-in. stone to make satisfactory removal of clay; and that a pebble phosphate containing 35% clay is fed at 100 t.p.h. to 3 @ 2×6-ft. scrubbers in series, with intermediate screening on 20-m. Hum-mers, producing a washed pebble cleaner than was made on log washers, with less loss, and with a saving of 66% in power and 50% in maintenance.

Stationary-screen washers must ordinarily be set on such a steep slope that insufficient time is available for even the most cursory washing.

At Lawrence Stone & Gravel Co., Blenheim, S. C. (*45 #9 RP 44*), an 8×10-ft. stationary screen, on 5° slope, with 8-m. aperture, forms the bottom of the dump box for a 10-in. dredge line. A blank plate parallel to and about 1 1/2 in. below the screen causes the undersize and water to surge up and down through the screen, both washing the gravel and preventing screen blinding.

7. CLASSIFIER WASHERS

The classifiers used for sizing coarse and intermediate sands are, in order of decreasing use: (*a*) sand tanks, usually of automatic-discharge types; (*b*) whole-current and surface-current settlers; (*c*) launder- or trough-type; (*d*) mechanical classifiers; and (*e*) hindered-settling hydraulic classifiers.

Sand tanks are usually of the continuous type with automatic control of sand discharge. See Sec. 8, Art. 8, for description and discussion of the forms commonly used in concentration practice.

Tilting tank. Fig. 11 shows a form of tilting tank widely used in cleaning concrete sands. Tank *a*, which is pyramidal, with a minimum side slope of 50° (better 60° or 65°)

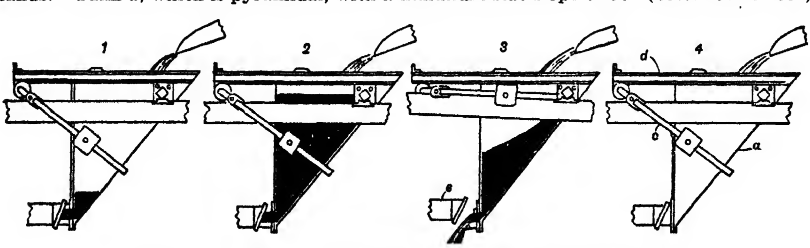

Fig. 11. Cycle of a tilting sand tank (*after Stephens-Adamson Co.*)

is supported near the back on knife-edge pivots, and is counterbalanced by the swinging arms *c*, carried at the outer ends of the cantilever frame *d* attached to the box, the mechanism being so arranged that as *d* tilts downward to the left, counterweight *c* is raised as shown in item 3, and the sand spigot opens by falling away from the fixed stop *e*. When the tank has emptied itself of sand, and has correspondingly decreased in weight, the counterweight *c* restores it to position with the spigot opening pressing against the closer stop. This may be a piece of rubber belt or softer rubber, suitably backed for stiffness, or a flatly conical rubber, wood, or metal plug.

Many forms of tilting tanks have been built. Sensitivity is increased by placing the counterweight on the opposite side of the fulcrum, increasing the horizontal projections of the distances from weight and counterweight to the fulcrum, and by lowering the latter toward the center of gravity of the system, but crankiness increases at the same time.

Fig. 12 shows a form of tank pivoted at *A* in which the counterweight arm *C*, pivoted at *B* on *D*, is so connected through arm *E* and bell crank *F* to valve plate *H* that as the

tank tilts and raises C, the bell crank swings up and out and the valve opening is thus increased over that caused by simple swing of the tank as in Fig. 11. Counterweight is set so that with the tank filled as indicated the weight of the small amount of additional sand necessary to cause water to back up on the feed side of baffle K and of the water backed up tilts the tank slightly; the relatively large valve opening permits rapid discharge and fall of sand with release of backed-up water, whereupon the valve again closes.

The cycle of the apparatus starts with the tank partly filled with settled sand and overflowing water and suspended material as in item 1, Fig. 11. Sand continues to build up (and the overflow tends to become coarser) until at, say, the condition shown in item 2, tilt occurs and a thick mixture of sand and water discharges as in item 3 until the counterweight restores at some condition as in item 1 before break-through of thin pulp occurs. The shorter the fluctuation of top-of-sand, *i.e.*, the more frequent the tilts for a given sand flow, the more uniform the product.

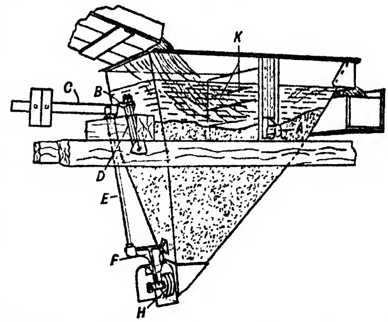

FIG. 12. Tilting sand tank with lever valve (*after Smith Engineering Works*).

Capacity of a tank depends upon the quantity of water overflowing, the separating mesh, and the dimensions at overflow level. For all practical purposes, all of the water entering can be considered as overflowing vertically, which gives a rising water velocity $V = Q/A$, where A is the tank cross-section at overflow level, Q is the volume of water flowing per unit of time, and V is velocity, the units being chosen to correspond. Settling velocities of the sands normally treated may be considered as lying in the Newton range (Sec. 8, Art. 1), and the equations for falling velocities there given apply. The determining sand size is that of the separating mesh. Free-settling prevails. Hence the maximum liquid volume that can be sent to a tank of a given size is that which will give an overflow velocity not to exceed that of the settling velocity of the grain of separating mesh; excess liquid will carry over coarser sand, a deficit in liquid will permit finer sand to settle.

Shaw (*44 #4 RP 47*) reports capacities as about 0.3 to 0.35 cyd. of coarse sand per hr. per cu. ft. of tank volume, and capacity for fine sands as 55 to 60% of those for coarse. Water capacity when catching coarse sand ranges from 10 g.p.m. per sq. ft. for 5-ft. tanks to 20 g.p.m. per sq. ft. for 12-ft. tanks; for fine sand, water capacity is about 75% of these figures.

Baffles. It is apparent that without some means of adjustment in overflow area, the character of the sand from such a tank will vary widely under the fluctuating conditions of stream flow normally prevailing. This may be compensated to a certain extent by installing a cross baffle (Fig. 12, item K) adjustable in its distance from the overflow lip. Only that part of the tank on the overflow side of the baffle is now to be figured for rising current, whence it follows that the rising velocity for a given water flow increases as the baffle is moved toward the overflow lip. If, at the same time, sensitivity is increased to the point that the fluctuation in top-of-sand is small, scour under the baffle enters as an element in determining size of overflow (see Sec. 8, Art. 8), and the cone becomes substantially automatic for a given setting of the baffle over a considerable range in feed volume. Adjustment in depth of baffle permits some control of sharpness of separation.

Spigot density of sand cones is given by Shaw (*44 #1 RP 37*) as ranging from about 30% water by weight for fine sands to 25% for coarse sands.

Spigot discharges at the above densities are at the rate of about 200 lb. solid per min. per sq. in. of spigot area for diameters of 2 1/2 in. or larger (*43 #10 RP 41*); discharge rate falls rapidly for smaller sizes (Sec. 8, Art. 12 and Fig. 41). Shaw (*43 #5 RP 49*) recommends that in calculating sizes for rougher-pocket spigots, an additional area of 20% over that required to discharge an equivalent volume of water under the same head be allowed to compensate for the sand content.

Whole-current classifiers in the form of sloughing-off boxes or V-tanks are useful for sand settling when rough sizing of the settled sands is desired. Action therein and design requirements and equations are given in Sec. 8, Art. 8. Usual sizes are 6 to 8 ft. wide at the top and 15 or 20 to 40 or 50 ft. long, with gates of slide or molasses type at about 5-ft. intervals. The shorter boxes are sometimes used as receiving boxes for dredge-pump lines, but the sizing that they effect is a disadvantage in this service, since the gate products must usually be mixed again for further treatment, and incomplete mixing results in uneven feed to the subsequent apparatus.

Surface-current classifiers are used for desliming fine sands, and at the same time effecting a size separation of the deslimed material. Analysis of action and design equations are given in Sec. 8, Art. 9. A form reported by Dull (*43 #6 RP 29*) is shown in Fig. 13. Spigots *a* are made of rubber hose with pinch clamps and are long enough to enable them to be swung over any one of the three dewatering conveyors *b*, thus permitting almost any desired blending.

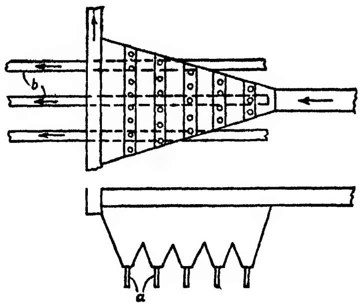

FIG. 13. A multispigot surface-current classifier (*after Dull*).

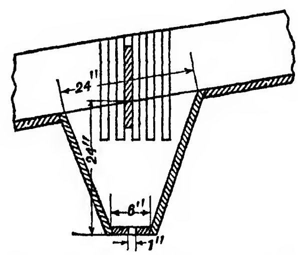

FIG. 14. Launder pocket for coarse or medium sands (*after Shaw*).

Launder classifiers are frequently used for bleeding off sands from flumes. The usual arrangement is one or more roughing pockets with adjustable baffles (see Sec. 8, Arts. 10, 11, 12) and a transverse slot in the bottom of the pocket (Fig. 14); if hydraulic water is used, a pressure pocket with spigot discharge is placed below the roughing pocket (see Sec. 8 as above). Dull (*43 #6 RP 29*) describes such an apparatus with 8 or 10 pockets along a length of launder such that all were visible to an operator centrally stationed; spigot discharges were regulated by molasses gates operated by means of levers from the station. Dull (*ibid.*) also describes an adjustable slicer (Fig. 15) for drawing off coarse sand; he recommends riffling a short distance ahead of the slicer in order to throw the sand into suspension and so withdraw only the quickest-settling material. See also Art. 20, Sec. 3.

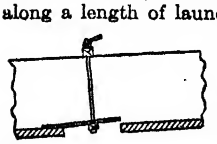

FIG. 15. Launder sand slicer (*after Dull*).

Scrubbing in flumes. Any flume or launder carrying coarse material causes a certain amount of rubbing together of the coarser, rolling lumps, and thereby does a certain amount of scrubbing. The action is accentuated by transverse riffling and by drops in the line (see Sec. 11, Art. 26).

At HEDRICK GRAVEL & SAND CO., Lilesville, N. C. (*45 #2 RP 42*), 200 t.p.h. of crude gravel with 20% clay and 2,000 g.p.m. is transported in an unriffled 2×250-ft. flume, on a 13% grade. Normally, sufficient disintegration is thus effected. If it is insufficient, provision is made for detour through a 6×24-ft. drum scrubber, the discharge of which re-enters the flume.

Sizing in flumes. Long-range products of one specific gravity stratify on a size basis in flumes, irrespective of the velocity of flow, but when the flow rate is such that the larger particles are never in suspension, the nature of the stratification is different according to the nature of the bottom of the flume. If the bottom is smooth, the large and flat grains form a slow-moving bottom layer, dragged along on the water-lubricated and substantially sand-free flume bottom by the frictional pull of the overlying material. This is the action in the trough washers used to remove flat slate and bone from the more rounded coal. The more rounded particles stratify more or less according to size above this lower layer, and progress by a combination of rolling and sliding. If, however, the bottom of the trough is riffled sufficiently to force rolling of the settled coarser particles, reverse classification (Sec. 11, Arts. 2, 26) occurs, and the material not in actual suspension stratifies with coarse on top and fine beneath. Thus by suitable combinations of bottom character, water velocity, and skimming arrangements, it is possible to use a flume to make rough cuts on long-range feeds of one specific gravity between flat and rounded coarse material, between intermediate sands and the remainder (an undercurrent, Sec. 11, Art. 26), between slime and the remainder, or between fine sand and slimes and the remainder.

Mechanical classifiers (Sec. 8, Arts. 2 to 7) are used both for grading and dewatering industrial sands (see Sec. 3), and for making a rough gravity-size separation of iron and manganese ores (Sec. 2). Their advantage over sand cones lies in the saving in sand fall

through the machine, a possible larger capacity per unit of mill volume, drier sands, and no possibility of choking of sand discharge. On the other hand, a sensitive automatic cone, well operated, probably makes a closer cut at the separating mesh, particularly with fluctuating feed.

Sizing test of one of the more siliceous concentrates made by a bowl-rake classifier on Mesabi ore is given in Table 2.

Table 2. Sizing-assay test on rake product of a bowl-rake classifier treating wash iron ore (*After De Vaney and Coghill, RI 3148*)

Dorr ore washer consists essentially of a combination of a standard rake classifier and a wash trommel. The trommel is mounted transversely above the classifier pool, at such a height that a lower segment is submerged, and material therein is, therefore, subjected to underwater scrubbing. Oversize is lifted to a discharge chute above pool level by a scoop device similar to that used in the discharge head of a grate ball or tube mill (Sec. 5, Fig. 56). The manufacturer reports that a 16×30-ft. machine has the capacity in iron-ore washing of 2 @ 6×25-ft. 2-log washers making 65-m. overflow, and a test on wash iron ore at Minnesota School of Mines is reported (*Bul 6 MSM*) in which the washer made 90% recovery against 88% in a log washer, and delivered a higher grade of concentrate. The data given in Table 3 are reported from Mahon and Counselman (*130 J 519*).

Shovel and sand wheels are used to a considerable extent for rough washing and dewatering. Typical forms are described in Sec. 15, Art. 1.

Dorrco sand washer comprises a shallow circular tank with flat bottom inclined at a slope of 4 i.p.f., and a slowly revolving wheel equipped with peripheral buckets, just clearing the tank bottom. Sand is picked up by the buckets, carried above water level onto an inclined drainage deck and is discharged therefrom through a chute. Excess water overflows a peripheral lip on the lower wall of the tank. The 12-ft. (diam.) unit has a rated capacity of 150 to 200 t.p.h. of sand. Rough separations are claimed possible at any mesh between 20 and 100, and it is asserted that the machine may be operated to deliver a sand product containing not more than 1 to 5% <100-m. fines. Moisture content of sand is higher than that obtained in drags and mechanical classifiers.

Hindered-settling hydraulic classifiers are used both for making multiple splits of industrial sands at meshes from 10 to 100, and also for desliming. Multiple-spigot machines, usually of the automatic-discharge type (Sec. 8, Art. 11), are used in grading service (Sec. 3) and for concentration (Table 5); hydro-bowls (Sec. 8, Art. 7) are used widely in desliming (Secs. 2, 3).

Performance of an 8-spigot automatic-discharge classifier making asphalt sand (*43 #7 RP 21*) **is shown in Table 4. Further data on performances of such classifiers are given in Sec. 8, Tables 36 to 39.**

Character of classifier-washed products. A hydraulic classifier puts together in the various spigot products the bulk of the equal-settling grains in the feed which are fairly presented to the spigot and capable of settling against the rising current therein, plus any more rapid-settling grains carried past the preceding spigots and now fairly presented, plus some grains too small to settle normally against the nominal rising current in the spigot, but which settle nevertheless because of entanglement in a crowded mass of heavier

a Overflow not sampled.

grains, or because of eddies in the sorting column. This distribution for a single-gravity feed to an 8-spigot hindered-settling classifier is shown in Fig. 16. For any given mesh size, grains of that size appear in a number of spigot products. Thus there are 28-m. grains in all spigot products; material amounts in *2* to *5*, some 4 or 5% in spigot *1*, and fractional percentages in the others. There are even fractional percentages of 200-m. reported in all, but this is probably due to abrasion in screening, at least in the coarser products.

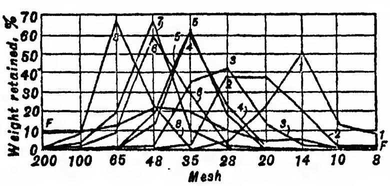

FIG. 16. Size distribution by an 8-spigot Fahrenwald sizer treating a single-gravity feed.

The 28-m. grains in spigot *1* are largely accidental, carried down by eddying and entanglement, since the current in this spigot was set for a 14-m. split. Even so, they average the most nearly spherical 20-m. particles in the feed, plus a few particles of heavier impurity. The 28-m. grains in spigot *2* and a majority of those in spigot *3* are substantially equiaxed; there is no prominent shape difference between them, but close examination shows that those in spigot *3* are somewhat flatter than those in spigot *2*. The 28-m. grains in spigots *4* and *5* are definitely flattened and/or elongated. These two spigots (as was also true of spigots *6* and *7*) were set to substantially the same rising currents in order to take care of the large amounts of 35- and 48-m. sands in the feed, hence there is not a great deal of difference in shape as between the two. The 28-m. grains in spigots *6* and *7* are mostly thin conchoidal shell-like fragments. A similar variation in shape of the grains of a given mesh size in successive spigot products holds all along the line, and is characteristic of closely classified products.

When the material classified contains grains of two (only) specific gravities, sizing curves of the products, plotted as in Fig. 16, show two humps, separated by a valley that is more or less deep and broad according respectively to the efficiency of the classification and the difference between specific gravities. With respect to either mineral, however, overlapping occurs as with a one-mineral feed.

When the feed is a natural primary ore containing free grains of both minerals and middling grains of all intermediate specific gravities, the curves lose the peaked character of Fig. 16, and become broad rounded humps with marked increase in overlap.

If the number of spigots is decreased the magnitudes of the overlaps between successive spigots increases. Thus the products plotted in Fig. 17 were made by combining spigots *1* and *2*, *3* and *4*, and *5* to *8* of the products of Fig. 16 and dewatering, with a certain amount of fines rejection, in rake classifiers. Thus the *1–2* and *3–4* products of Fig. 17 both contain 25 to 30% of 28-m., and *3–4* and *5–8* both contain 30 to 35% of 40-m. Percentages of such magnitude go far toward setting the average sizes of the products of which they are parts.

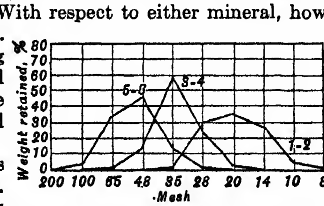

FIG. 17. Sizing tests of combined products of the classifier of Fig. 16.

Nonhydraulic classifiers making two products only, such as the sand tanks and mechanical classifiers, show even greater overlaps. Thus if such a classifier is run for, say, a 100-m. split with not over 2% of <100-m. in the sands, there will be considerable amounts of 48-m. and probably, even, some 35- or 28-m. material in the overflow. If, on the other hand, <100-m. overflow is the aim and not over 2% >100-m. therein is allowable, the sands will contain 20 to 50% of material finer than the separating mesh (see Sec. 8, Arts. 4 to 8). This explains the necessity of placing a hydro-bowl or other sand settler as a guard behind mechanical classifiers in sand plants when there is a deficit of fine sands, and the advisability of desliming ahead of the mechanical machines when clean sands are wanted.

8. MISCELLANEOUS SCRUBBING AND WASHING

Many problems encountered in beneficiating ores and industrial minerals by scrubbing and washing methods are not solved by the standard apparatus and methods previously discussed. For these cases appeal is usually had to standard ore-dressing machines of other types, or to simple modifications of these.

Clay balls are formed when tough clays, resistant to penetration by water, are tumbled. Such clay masses tend to float on the balance of the material in tumbling and not to be nipped and subjected to the disintegrating forces. A number of methods have been tried to deal with them, none too successfully. These include crushing in smooth rolls (*41 #8 RP 34*), in corrugated rolls, or in toothed rolls, in each case preferably operated with only one roll driven so as to subject the material to a tearing force; special three-roll machines in which adjacent roll faces move in opposite directions, designed to accentuate the tearing effect; impact mills of the hammer type; pug mills (*41 #8 RP 34*); soaking, usually accompanied by the use of monitors or a plurality of high-pressure jets; or, as an acknowledgment of failure, separation on a screen and discard, together with any and all of the wanted material that they may have rolled up in their travels. Such discard is usually economical when the concentrate has low unit value, *e.g.*, phosphates; it is certainly questionable when the concentrate is tin or gold. The nearest to a satisfactory solution reported is a hammer mill with a slow-moving breaker plate, independently driven (*34 #10 PQ 52*).

At Virginia Limestone Corp., Ripplemead, Va. (*43 #12 RP 26*), clay balls were disintegrated by passing the crushed stone, before final washing and sizing, through a 1,000-cyd. bin, 40 ft. deep, through which about 100 g.p.m. of water from washing screens trickled. The bin was kept reasonably full, and the pressure and working of the mass in moving toward the outlet, together with the water, were effective.

Unsound stone is ordinarily eliminated to a satisfactory extent by log washing or by light crushing and rescreening; if it is of sedimentary character, *i.e.*, shale or soft sandstone, which tends to form flat particles in gravels, it can be removed by jigging in the coarser sizes and tabling in the finer (*43 #1 RP 67*). These apparatus also float over chip stone, clay balls, and wood. Some decrease in the content of flat stone is also possible by rescreening over slotted screens, but the separation is relatively crude. Use of an impact crusher is reported (*44 #2 RP 49*) to have reduced rattler loss from 45% to 30 or 35% in one case.

Iron, if it is a problem at all, is usually a serious one because of low tolerances in specifications. Iron in glass sands, if in the form of metallic iron, or magnetite or ilmenite grains, is readily removed from dried sized sands by magnets; if the grades have been prepared by classification, the iron-bearing grains are usually sufficiently finer than the prevailing size to screen out. Hematite grains are usually removed by wet tabling, but dry tabling and electrostatic methods are both applicable. Iron-bearing incrustations can sometimes be reduced somewhat by vigorous scuffing, but are usually best removed by acid leaching and subsequent washing.

Dry scrubbing consists in tumbling material in a dry state, usually on a revolving screen.

At Granite Rock Co., Watsonville, Calif. (*43 #7 RP 33; ibid. #8, 22*), 1 @ 4×12- and 1 @ 4×10-ft. 2-deck vibrating screen were used for rescreening an average flow of 180 t.p.h. Newly crushed dry gravel sizes contained about 0.25% dust, but the fine sizes (1/2~1/4-in., 3/8~1/8-in., and 1/4~1/8-in.), when taken from stockpiles (which never dried out), contained up to 2.5% dust after rescreening. Substitution of wet washing brought the <200-m. in washed products down to a trace.

SECTION 11

GRAVITY CONCENTRATION

1. PRINCIPLES

Introduction. Gravity concentration is the method of separating grains of minerals of different specific gravities by reason of their differences in movement in response to the joint simultaneous actions upon them of gravity and one or more other forces. In the great majority of gravity-concentration processes and apparatus the other force used is the resistance to downward penetration offered by a medium that has more or less fluid properties—a gas, usually air; water or some homogeneous liquid; or a mechanical mixture of a fluid and a particulate solid maintained more or less in suspension. The fluid properties utilized are density and viscosity; the forces which they bring to bear are buoyancy and upward impulse. In other gravity processes the impulse of moving fluids is caused to act at an angle approximating 90° to the vertical action line of gravity, and friction between the particles and a solid supporting surface at rest or in motion is an important element in the resultant movements of the particles.

In all gravity processes there is also an element of sizing. It is not difference in specific gravity that causes the differences in movement of particles, but the differences in their weights in the common medium. Hence a particle of a given high specific gravity and small size will have the same movement in a given fluid medium as another of lower specific gravity and greater size. Therefore, since all natural mixtures of broken grains have a long size range, it is necessary, if separation is to be effected, to superimpose size control, in order to make the motions of the particles of different specific gravities effectively differential.

Mineral mixtures susceptible to separation by gravity are those in which valuable mineral and gangue differ appreciably in specific gravity, *e.g.*, quartz or any usual rock

matrix (sp. gr., 2.6 to, say, 3) and a sulphide mineral (sp. gr., 4 to 7.5); or mixtures in which an apparent weight in the medium, appreciably different from the real weight therein, can be induced preferentially in one of the minerals, as by attaching air bubbles or a liquid film, or by agglomeration of a number of small particles into a larger aggregate.

Concentration criterion. The important criteria in determining whether and what kind of separation is possible in a particular case are the specific gravities of the minerals, the specific gravity and viscosity or plasticity of the separating medium, and the mechanical methods available for utilizing (and possibly accentuating) the differential particle movements induced by the difference in the specific gravities of the solids. The first two criteria may be combined in the ratio $(S_H - R)/(S_L - R)$, where R is the specific gravity of the medium and S_H and S_L are the specific gravities of the heavier and lighter minerals respectively. The quotient is the CONCENTRATION CRITERION. Neglecting, for the present, the viscosity of the medium and the mechanical means to be employed, it may be stated generally that when the concentration criterion is negative or a positive number greater than 2.5, separation will be easy at all sizes down to the finest sands; at 1.75, commercial separation is readily possible down to 65- or 100-m.; at 1.5, separation becomes difficult, and the commercial lower size is about 10-m.; at 1.25 commercial separation is still possible at gravel sizes but not, in general, at sand sizes; below 1.25 commercial separations by gravity concentration without differential weight modification are not presently possible.

Theory. Most of the attempts at theoretical explanation of gravity concentration have taken the form of assertions that Stokes' and Newton's theoretical formulations of the resistances of fluids to penetration by individual particles (Sec. 8, Art. 1) are applicable, with more or less modification. Both commercial practice and laboratory experiment with models of mill apparatus have shown, however, that this is not the case. Nor should it be true, since in commercial operation particles are invariably crowded to an extent that collisions with other particles affect their behavior materially, and the uniform true-fluid flows upon which the theoretical formulations are founded are conspicuous by their absence. The most that can be said for the use of these mathematical formulations in gravity concentration is that they are useful to indicate the character of fluid resistances and, consequently, the probable direction of the effects of changes in fluid conditions, but that attempts to quantify any particular case by their application bid fair to result in failure.

On the other hand, much can be learned by visual and instrumental study of the character of the media in which gravity concentration occurs and of the behavior of particles of different specific gravities and sizes in these environments, when the latter are varied within ordinary operating limits. Results of such studies are presently available, and certain generalizations based on them follow.

Separating media in which concentration is effected may be classified, on the basis of bulk movement with respect to their containers, as flowing and stationary. FLOWING MEDIA exert forces on the particles to be separated that are of the nature of impulse; in other words, their separating function depends primarily upon the rate at which they are moving. STATIONARY MEDIA, on the other hand, while frequently in motion within their mass, do not offer resistance to penetration by reason directly of the impulse connected with such motion, but rather by reason of buoyant and plastic properties of the media which these possess inherently or take on as a result of the agitation to which they are subjected.

Flowing media may have more or less vertical, or more or less horizontal resultant directional components. In general the fluid is air or water. Vertical currents are typified by free-settling classifiers (Sec. 8, Art. 10). These apparatus are utilized as concentrators only in unique circumstances (*Vertical-current washers,* Art. 35).

When the direction of the flowing medium is more or less horizontal, the separating particles follow different resultant directions according to environment; if they are free-falling in the medium, the form of the path is the trajectory of a particle under the influence of some initial forward velocity, *i.e.,* that of the transporting current, and the vertical resultant of the gravitational and resistant forces (see *Sloughing-off boxes,* Sec. 8, Art. 8). If the gravitational force is resisted by a substantially horizontal support, the particles proceed in the general direction of the current flowing downhill over this surface; in this case the particles are subjected to scour, which causes them either to roll or to proceed by a series of leaps (*PP 86 USGS*). (See *Film sizing,* Art. 32, and *Sluices,* Art. 26).

Stationary media comprise heavy liquids and solutions, and solid-fluid suspensions of varying degrees of concentration of solids. A BED is a suspension in which the solid is in the form of grains, ranging in size from sand to gravel; it is impregnated with a fluid, usually water; the whole is supported and confined in a receptacle, and is subjected to agitation, ordinarily but not necessarily intermittent. The majority of gravity concentrators utilize beds. Beds are further characterized by the fact that each grain is in substantially continuous contact, of varying intensity, with all grains immediately surrounding it; further, the bed has fluid characteristics only when dilated. STATIONARY BEDS are substantially undilated; SEMISTATIONARY are dilated. For details of formation and action see discussions of the various types below. A QUICKSAND is a suspension of lower solid concentration than a bed; the sizes of the grains are usually finer; the sustaining agitation is normally rotary or vibratory, if mechanical, or is due to flow of the impregnating liquid, and is of low intensity; the grains make much less

frequent and lighter contact with less neighbors; they are continuously dilated and continuously fluid. Quicksands are utilized primarily in sink-float processes (Art. 28). SUSPENSOIDS are characterised by fineness of solid and the fact that they are maintained, in large part at least, by thermal agitation of the liquid transferred through an ionic swarm surrounding the solid (Brownian movement, *87 A 217*).

Resistance of mixtures to penetration. When attempt is made to cause a solid particle to penetrate mixtures of solid particles and a true fluid, it is found that the resistance varies according to the size and interstitial spacing of the solid particles of the mixture, the specific gravity and shape of these particles, the character and velocity of the interstitial fluid, and the size, shape, and orientation of the penetrating particle. Part of these resistance properties are familiarly characteristic of the behavior of true fluids. The mixtures, however, have two further and less familiar characteristics, *viz.*, (*a*) that their resistance to penetration decreases, within limits, with increase in agitation, and (*b*) that with a given degree of agitation, resistance is a maximum for sizes of penetrating particle that are less than that of the mixture particles (where these are closely sized) and greater than the interstitial spacings of these particles. The first of these characteristics is not a property of true fluids; the latter finds a parallel, however, in the action of gases, the resistance of which becomes less than predicted by Stokes' law when the diameter of the penetrating particle approaches the mean-free-path of the gas molecules. (Millikan, *The Electron.*)

Density of a fluid-solid mixture (weight per unit volume) is called the COMPOSITE DENSITY; the frictional resistance to penetration is the PLASTIC RESISTANCE: total resistance to penetration is buoyancy plus plastic resistance, and is called the EFFECTIVE DENSITY. It may be measured by determining the density of a particle which will neither rise nor fall in the mixture.

Dilation of a bed or quicksand is due to transformation of the kinetic energy of the rising true-fluid into an equivalent upward static pressure, which is a substantial constant for any given bed irrespective of the degree of dilation, but which differs for different beds according to the size and specific gravity of the component grains. In other words, the back pressure exerted by a stationary bed at any given point in it is equal to the back pressure exerted by the overlying grains irrespective of their state of dispersion and consequent height above the point of measurement. It follows that since the upward static pressure at a given point in a bed is independent of the composite density of the bed, the gravitational (true-density) resistance of the bed with respect to individual particles should be independent of the composite density, although important so far as relative vertical position to other beds is concerned, and that the important element in the resistance to individual particles is the effective viscosity. This falls rapidly with increased dilation, so that penetration of highly dilated quicksands is much easier than that of just dilated beds of the same particles.

Reverse classification is the name applied by Dyer (*127 J 1030*) to the stratification by size, large particles at the top, which takes place with more or less completeness in a long-range bed. It is caused by the early interlocking of the large grains in compacting. The fine grains, not interlocked so soon, remain free to trickle down through the interstices of the larger. These fine grains thereafter resist subsequent penetration by the large grains and thus hasten the stratification. Strong rising currents of interparticle fluid tend to prevent trickling. The phenomenon is an important part of shaking-table and sluice operations.

Fundamental principles of gravity concentration may be summarized as follows:

1. Solid particles acting under the influence of gravity overcome the resistance of media in which they are immersed, or resist the impulses of such media, in proportion to their immersed weights. Since the immersed weights are proportional to the volumes and to the densities of the particles, specifically that:

(*a*) Particles of the same specific gravity but different sizes fall in a given medium at rates which increase as particle diameter increases.

(*b*) Particles of the same size but different specific gravities fall in a given medium at rates which increase with increase in specific gravity.

(*c*) Rules 1*a* and 1*b* may be modified by differences in particle shape, flat particles falling most slowly and equiaxial particles most rapidly, all other things being equal.

(*d*) Resistance of particles to rolling scour depends upon the extent of projection above the supporting surface and upon the immersed weight; small, flat, and high-gravity particles have maximum resistance; large, equiaxed, and low-gravity particles roll comparatively readily.

(*e*) Resistance of particles to leaping scour and to suspension in a scouring stream is greater the greater the immersed weight, shape being the same; for particles of different shapes and equal immersed weights, equiaxed and acicular particles are more resistant than flat.

2. Resistance of media to particle fall increases with increase in effective density and viscosity.

3. Scouring capacity of media increases with increase in effective density.

4. Effective density of a medium is dependent both on its degree of dispersion and upon the size of the penetrant.

(*a*) As against superinterstitial particles (see p. 05) the order of effective densities is: stationary beds semistationary beds >quicksands >suspensions.

(b) **As against** par-interstitial particles (see p. 05) the order is as in a.

(c) **As against** subinterstitial particles (see p. 05) the order depends not only upon relative sizes of penetrant and medium particles, but upon the chemical composition of the penetrant, and upon the composition, specific gravity, and chemical composition of the interparticle liquid. For details see discussion of particular machines.

Classification of processes and apparatus based on the type of medium employed for separation, follows:

BEDS:

Compacted (Stationary):
None. Jigs with a sub-bed of ragging (Art. 13) are the closest approach.

Dilated (Semistationary):

PULSATED:
Jigs.

SHAKEN:
Shaking table, pan, rocker, vanner.

STIRRED (vibrated).
Sluice, kieve.

QUICKSANDS:

Artificial:
Chance cone.

Self-made:
Robinson washer, diamond pan.

Suspensoids:
Heavy-media cones, differential-density separators.

LIQUIDS:

Heavy:
Sink-float with aqueous solutions and with heavy organic liquids.

Water:
Buddles, strakes. Also used as the interparticle liquid in all previous classes.

GAS:
Blowing. Also used to form semistationary beds on some forms of jigs and shaking tables, and an air quicksand.

BEDDED MEDIA

The processes and apparatus using dilated beds as the principal means of separation comprise a majority of the older machines. Jigs utilize pulsated beds in which the impregnating fluid is usually water, but may be air. Pans, rockers, shaking tables, and vanners use beds formed and maintained by shaking as the primary separating means, supplementing them by film sizing for cleaning concentrate. The kieve and the sluice use beds formed and maintained by stirring; the former utilizing a paddle, the latter the scouring and eddying impulses of water flowing with considerable velocity.

JIGGING

2. PRINCIPLES OF JIGGING

A jig is a mechanical concentrator that effects separation of heavy grains from light by utilizing differences in the abilities of the grains to penetrate a semistationary bed. Essentially it is a box with a perforate bottom and no top, in which a relatively short-range separating bed is formed by pulsating water currents. These currents may be all upward, all downward, or alternately upward and downward; if the last, they may have equal accelerations and velocities in both directions, but usually do not. The velocity of the water currents is variable throughout each cycle. Diagrammatic curves for the three cases stated are shown in Fig. 1.

Terminology. The bed is the entire mixture of solid and liquid in the jig box; it is LOADED when operating with continuous feed and discharge of products; it is UNLOADED when pulsating normally but neither being fed nor discharging; it is EXPANDED when loosened by pulsation, and COMPACTED when

the grains have all settled back into positions so that the jig box constitutes their entire support. A LAYER is a stratum of a bed in which all of the particles are of substantially the same specific gravity. The grains being treated are referred to as SUBINTERSTITIAL when of such size that they can pass through the interstices of the bed without other than glancing contacts. SUPERINTERSTITIAL particles are those too large to penetrate the interstices without displacement of the bed particles. PAR-INTERSTITIAL grains penetrate the bed along interstitial passages without apparent displacement of the bed particles, but with constant scraping and turning, stopping each time the bed compacts; they are the particles ranging in size from the interstitial spacing in a fully expanded bed to something slightly larger than the spacing in a compacted bed. When expansion is effected by moving the jig box up and down in a body of water, the jig is of MOVABLE-SIEVE type; when the box is fixed and the water is moved, the type is FIXED-SIEVE. A PLUNGER JIG is one in which the water movement is caused by a reciprocating plunger; in a PADDLE JIG, by a paddle; and in a DIAPHRAGM JIG, by a diaphragm. In a PULSATOR JIG water impulses are due to pressure changes caused by a rotating valve between a pressure source and the water.

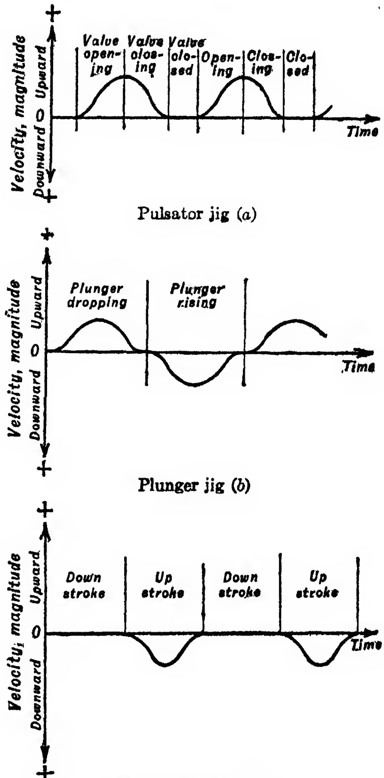

FIG. 1. Diagrams of jig currents.

Action in a jig. A dangerously simple picture of action in a jig may be had by charging a hand screen with a short-range pulp coarse enough to be retained and moving the screen up and down in water in a tub, at such a rate that the screen support drops from the bed on the down stroke, with such an amplitude that water does not flow in over the top of the screen on the down stroke nor does the surface of the bed emerge from the surface of the water on the up stroke. Following such treatment the bed will be found sorted into layers, the bottom one composed of the heaviest mineral, the top of the lightest mineral, the middle a mixture, indefinitely layered, of free minerals of intermediate specific gravities, and of locked-middling grains.

But while this pictures the performance of a hand jig (Art. 12), it does not represent the essential actions of a continuous jig. In such a jig the sorted bed already exists, and the new feed, comprising grains of all of the different sizes and varieties of those of the bed (and usually some finer), is flowed continuously into one end of the box, reject is overflowed continuously from the other end, and material is also continuously drawn from the bottom layer. A diagrammatic sketch of this action is shown in Fig. 5. (See detailed discussion of the figure.) At the moment it is sufficient to note that the bottom layer is the separating layer; that, in effect, it is a constant body of semifluid character and relatively high effective density; that when feed is presented to it, it takes in particles of the same specific gravity as that of its constituents, while all particles of lower specific gravity float on it and flow as a plastic stream to the overflow weir.

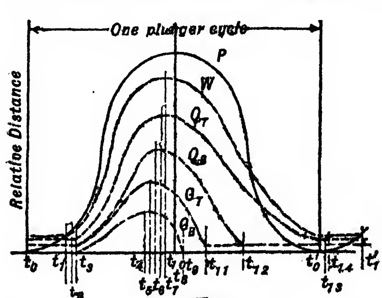

FIG. 2. Diagrammatic analysis of movements in a plunger-jig bed.

Vertical movement of the layers in an unloaded bed in a plunger jig (Arts. 3 to 6) is indicated in Fig. 2. *P* represents the motion of the plunger, plotted as though it underlay the screen. Its amplitude is greater than that of any part of the bed. Water (curve *W*) starts to rise at time t_1. The lag is due to slow return of water through the bed, loss over the tailboard during the stroke, and open flap valves on the jig plungers. The water starts upward

abruptly at t_1, as the plunger meets the water surface in the plunger compartment, but the rate of rise is less than that of the plunger because of slip; W falls steadily relatively to P and reverses at t_8 somewhat before the plunger has reached the end of its impulse stroke. At the start of its fall, the water tends to follow the plunger closely, but as soon as the galena layer begins to settle and compact (t_9 to t_{11}; see below), the flow is hindered increasingly until a minimum level is reached at t_{14}, whence level rises slowly with entry of plunger water until t_1'.

Curve Q_T is for the top of the quartz layer. The small and flat grains, responding quickly to interstitial water movement, start to lift at t_2. At t_3 back pressure built up by interstitial friction causes the bottom of the galena bed to rise (G_B), lifting all above it, and imparting additional upward velocity to Q_T by force transmitted through the as yet partially compacted layer. Motion Q_T gradually decelerates owing to the settling velocity of the quartz in water until at t_7 Q_T reverses. At t_8 the quartz grains are accelerated by the water. Shortly thereafter, the bottom of the galena layer comes to rest, consolidation of the bed begins, and the resistance of the screen and side walls begins to build up through the consolidating layers, hindering the further fall of the top part, so that its falling rate decreases relative to that of the water and finally comes to rest at t_{13}. Similar analyses develop curves Q_B (bottom of quartz layer), and G_T and G_B for the galena layer. For detail see *153 A 442*.

Expansion of the bed starts at the top of the quartz layer at t_2 and increases until the bottom of the galena layer comes to rest at t_9. Compaction occupies a longer time, not being complete until the top of quartz comes to rest at t_{13}. Dilation is not uniform throughout; the top of a layer is more compact on the average than the bottom.

Penetration of a jig bed. The factors governing resistance of a bed to penetration were listed in Art. 1. A stationary bed cannot be penetrated by a solid which is larger than the bed interstices unless the weight or impulse of the applied solid is so great that a force of the general order of magnitude of a crushing force is imposed; hence the effective density of such a bed with respect to such a particle is relatively infinite. Since the composite density cannot exceed that of the bed particles, it is apparent that plastic resistance must comprise a very large part of the effective density. On the other hand, a particle smaller than the interstitial spaces of such a bed meets only the resistance of the interstitial fluid, in so far as its falling path is truly interstitial. With respect to such a particle, therefore, the effective density is that of the interstitial fluid. Hence the stationary bed is characterized by a transcendent plastic resistance against large particles and a small, but not negligible viscous resistance to small; composite density is the same for both, but effective density is substantially infinite for superinterstitial particles and falls discontinuously to that of the true fluid for subinterstitial particles. Hence superinterstitial and par-interstitial particles cannot penetrate a compacted jig bed, but subinterstitial particles can penetrate it freely in either direction.

The mechanism of penetration of a more or less expanded bed by superinterstitial and par-interstitial particles is illustrated diagrammatically by Fig. 3, which represents a sphere, somewhat larger than the

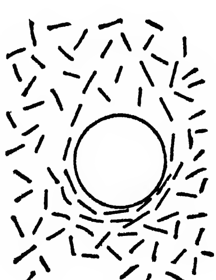

FIG. 3. Large sphere sinking through a jig bed.

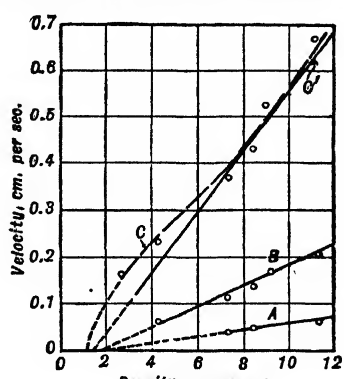

FIG. 4. Settling velocities of metal spheres in a 10∼14-m. jig bed.

bed particles and of the same or slightly greater specific gravity, sinking through the bed. The particles below it and, to a certain extent, those at the sides, are pressed together, face-to-face, with their longer axes roughly parallel to the sphere tangents at the points of contact. This compression of the surrounding bed is marked, even in the upper parts of the bed, where, without such closer packing for comparison, the bed appears undilated. As the penetration proceeds these onion-shell-like layers open immediately in front of the sphere and close in behind it in the form of an indistinct wake, but there is actually no visible vertical displacement of the bed particles. Bed-size particles of heavier minerals act like the large spheres but the disturbance of the bed is less widespread. It is the resistance of the bed particles

to crowding plus the frictional engagement of the penetrating particle with the bed particles past which it slides that constitutes for these the plastic resistance of the bed.

Par-interstitial particles heavier than bed particles penetrate without visible disturbance of bed particles other than those that they actually touch. It does not follow, however, that they therefore penetrate more rapidly than larger particles. Actually they must worm their way through interstices offered in the expanded bed; they cannot crowd a direct path through. Hence plastic resistance is a maximum for them.

Fig. 4 (*153 A 442*) shows settling velocities of relatively large spheres of different densities in short-range quartz beds. Curves *A* and *B* are rates in the upper 1 in. of a 3-in. bed; curve *C* is for the entire bed. Mean composite density of bed *B*, based on solid present and mean volume, was about 1.6, and for bed *A*, 1.8. The density of sphere for zero velocity, by extrapolation, is slightly higher, *i.e.*, these are the effective densities for 3/8-in. spheres. But effective densities are greater than 2.6 for par-interstitial grains, and equal 2.6 for bed-size grains.

Sorting action in a jig bed is affected by the specific gravity, size, and shape of the grain. Fig. 5 shows paths according to specific gravity and size. Flat grains of a given mineral and size are always near the top of a layer of that mineral; equiaxed grains at the bottom.

Notation. In Fig. 5 *G*, *Q*, and *M* stand for galena, quartz, and locked middling respectively; the subscripts $_{Sp}$, $_{Sb}$, and $_P$ for superinterstitial, subinterstitial, and par-interstitial respectively, and *B* for bed-grain sizes, with sub-subscripts $_L$ for the larger and $_S$ for the smaller grains, as needed. *H* preceding *M* differentiates the middling as heavy. *Sl* stands for slimes.

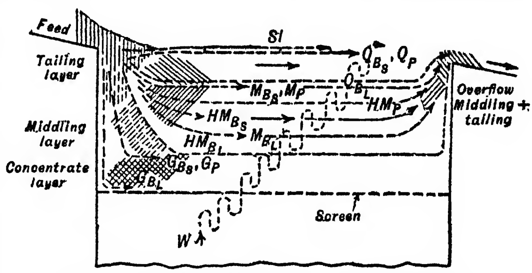

FIG. 5. Flow and distribution in a loaded jig bed. (For legend see discussion.)

Discussion. Fig. 5 represents, for simplicity, a loaded bed from a two-mineral ore (*e.g.*, galena in a quartz gangue), sized at the top only, *i.e.*, a long-range natural product. When this feed, represented by vertical hatching, comes on to the bed, it persists for a short time in its original mixture, then the various constituents begin to follow different paths as indicated. Slime of all mineral varieties flows in suspension along the top and over the tailboard. Small and flat bed-size quartz (Q_{B_S}) constitutes the top of the layer of quartz sands (indicated by down-to-the-right hatching), and par-interstitial quartz Q_P travels along with it, penetrating more or less slightly, depending upon the looseness of the expanded bed and the strength of the SUCTION (water down-flow) stroke. Large equiaxed quartz (Q_{B_L}) penetrates rather quickly to the bottom of the quartz layer but cannot penetrate the middling layer; it travels along with the quartz layer as a whole toward the tailboard and then is pushed up by the rising middling and overflows with it. Quartz of all sizes between Q_P and Q_{B_L} flows along in the mass of the quartz layer, somewhat stratified according to size and shape, and also overflows.

Galena of par-interstitial and bed sizes falls almost immediately to the bottom (cross-hatched) layer and distributes itself by size in the same way as the quartz. This layer does not, however, have general longitudinal flow. There is, of course, a gradual flow toward the drawoff (see descriptions of specific jigs), but this is usually so slow as not to be noticeable, and to all intents and purposes this lower bed may be considered stationary so far as horizontal movement is concerned.

Middling is of all specific gravities between quartz and galena. If given time, all of the grains of a given specific gravity from par-interstitial to bed-grain sizes would come to a given level and form a layer. Practically, there is a general sorting by specific gravity in which heavy middling of a given size underlies lighter middling of the same size, but large grains of lighter middling often underlie small grains of a heavier middling. This means that the layer tends toward a uniform composite density from top to bottom, thus the more effectively floating the quartz layer.

Buoyancy of a layer. As already indicated, a grain of par-interstitial size or larger cannot penetrate downward into a bed layer composed of grains of higher specific gravity. It may, if large enough, submerge partially, as a block of pine in water, but there it floats. It will probably not be lifted out by the rising stream at the end, although it may be. Too many such grains, floating at the surface of a layer, tend to screen off access by grains that should enter the layer. Hence the desirability of excluding tramp oversize from jig feed.

Subinterstitial grains penetrate independently of the composite density and plasticity of the bed. Their movement apparently depends upon a combination of differences in free-settling rates in water (Sec. 8, Art. 1) and differences in resistance to scour by roughly horizontal water currents (Sec. 18, Art. 16). The small particles pass through the interstices of a bed of relatively coarse particles (RAGGING), partly in suspension and partly by being scoured along the upper surfaces of the individuals composing the ragging. The scouring and suspending forces are maxima at or shortly after the time t_1 (Fig. 2), when the rising current is approaching full velocity and the ragging has not yet begun to expand and enlarge the interstitial passages. The small particles in suspension at this time, which are predominantly the slower-settling, lighter particles, respond immediately, of course, to this current and begin to rise through the ragging. The light particles settled on the ragging, presenting greater surfaces in proportion to their weight than the heavier, likewise roll and leap and are the first of the

settled material to go into suspension. The largest of the heavy small particles are rolled along on the supporting surface to a crevice and fall, never going into suspension at all. Hence throughout the period from t_1 to t_5 preferential rise of light particles is favored.

Interstitial currents. The falling currents of water are slower than the rising, as is evidenced by the fact that air collects under both the sieve and plunger of a plunger jig. The same conclusion can be reached, of course, by analysis from Fig. 2, bearing in mind that the returning force on the water is simply gravity, which is much less than the positive push of the plunger. This is indicated by the curve marked W in Fig. 2. Since the actual falling rates of the small particles are negligible by comparison with the interstitial water velocities, and the interference with fall and rise by the particles of ragging are substantially the same, the particles that remain in suspension and those that are readily scoured into suspension pass over the tailboard with the overflow water. Substantially only those that resist suspension pass down through the ragging.

Summary of bed action in jigs, in terms of what it does, follows:

(*a*) The lower layer of the bed will exclude from itself all grains of lower specific gravity than that of the grains composing the bed, within the size range of the grains composing the bed.

(*b*) Grains of equal or greater specific gravity than the bed will enter it irrespective of size range, except that larger grains, if flat, may not enter unless started on edge, and grains much smaller may be excluded by making the mean rising-current velocity distinctly greater than that of the downward current.

(*c*) The top layer of the bed will, in general, be penetrated by all particles fed, if the jig is being properly operated, except that those particles small enough to remain in suspension in the water move with and are governed by the flow of the water rather than by any action of the bed.

(*d*) The central layer of the bed excludes all grains of lower gravity than its own, within the size range of its own grains. It, therefore, stops all the coarser grains of gangue from further penetration. It passes all specifically heavier material. Its own substance, being prevented from passing downward, builds up at the expense of the low-gravity upper layer, which is thereby forced to overflow.

(*e*) The finest size of grain that can be maintained in a bed is determined by the apertures of the perforate support and by the velocities of the water currents in the bed interstices; particles too small to settle out of these currents cannot deposit; subinterstitial particles that deposit are usually fine enough to pass through the screen.

(*f*) Particles of light mineral smaller than the bed particles can and will penetrate even the lowest stratum of the bed, if the jig is so run that this layer opens sufficiently on the pulsion stroke to receive them, and if the mean downward water velocity exceeds the upward. Such penetration is even more ready in the case of small middling particles.

(*g*) If a bed is made too loose, its resistance to penetration by grains of its own size range is decreased and the grade of concentrate falls.

Maximum practical feed size for heavy ores is about 1.5-in.; 3-in. material has been handled, but not very satisfactorily. The average upper size limit for short-range feeds at the present time is about 0.5-in. and the minimum about 1-mm. Scalping of long-range natural feeds, as by placing jigs in ball mill circuits, particularly in mills treating gold ores, is increasing; as is also the use of jigs in rougher-cleaner arrangement in conjunction with or replacing table sluices on both gold and tin dredges. Minimum sizes that a jig will save are difficult to state. Some recovery of sulphide minerals is made along with the gold in grinding mill circuits, but this is largely incidental; for gravity treatment of ores of normal sulphide-gangue gravity differences, at sizes less than 2-mm., shaking tables are preferred. The maximum feed size in coal jigging is 6-in., minimum $^1/_8$-in.

Feed-size ratio (defined as the ratio of the aperture passing the largest grain of light mineral to that retaining the smallest grain of heavy mineral) in jig practice averages far below either the free- or hindered-settling ratios (Sec. 8, Art. 1) for the constituent minerals. Average for 12 plants treating ores with apparent concentration criteria ranging from 2 to 4 was 1.7, and the range 1.2 to 2.8. This is, of course, because the actual separations required were between pure mineral and rich middling, and/or pure gangue and poor middling, and the attempted concentration criteria were close to 1.0. In roughing service to obtain concentrate, where tailing is to be retreated, size ratios are what falls with natural or lightly deslimed feeds, crushed only to the size that liberates a reasonable amount of valuable mineral; the impoverished middling constituting the other product of such operations is always treated further.

Types of jigs. Jigs are classified on the basis of the method of effecting dilation of the bed. Thus, broadly, there are FIXED-SIEVE jigs, in which the dilating fluid, usually water, is caused to pulsate while the bed is stationary in space; and MOVABLE-SIEVE types in which the bed as a whole moves in a stationary body of water. Fixed-sieve jigs are subclassified on the basis of mechanism. Thus they are of PLUNGER TYPE when the water is caused to pulsate through the sieve by reciprocation of a plunger; PADDLE type when the impulse comes from a paddle; AIR-PULSATED when movement is due to alternate expansion and contraction of a confined body of air; DIAPHRAGM type when the plunger edges are sealed to the wall of the chamber by a flexible seal which allows movement of the plunger but prevents flow of water past it; and PULSATING when water comes to the under side of the screen from a closed chamber supplied with water through a pulsating valve.

FIXED-SIEVE JIGS

3. HARZ JIG

Description. The Harz jig is shown in Fig. 6. It consists usually of a plurality of separate and independent rectangular hopper-shaped compartments, with the upper part subdivided by a shallow longitudinal partition into screen and plunger compartments. The screen is fastened to grate *K*, which is held in place on the lower, fixed liners by upper liners that are held in by wedges. Reciprocation of the plunger causes flow of water through the screen. Feed enters the first screen compartment through slot *b*. The longest plunger stroke and consequently the highest water velocities are maintained in this compartment. The heaviest particles settle to the screen, and those smaller than the screen aperture pass through into the lower part of the compartment, called the HUTCH; coarser heavy particles collect on the screen until a bed is formed, when they pass under hood *F* and over the lip into spout *J*; light material passes over tailboard *C* into the second compartment, where it is subjected to currents of lower velocity, whereby the heavier part of the remaining material is removed while the lighter goes on into the third compartment, and so on.

Performance of Harz jigs. Settings for the treatment of short-range lead-zinc ores at CLAUSTHAL (*100 J 425*) are given in Table 1. Practice on a lead-silver ore at SILVER KING COALITION is shown in Table 2. BUNKER HILL & SULLIVAN mill uses 2-compartment Harz jigs to produce galena concentrate from the first and middling from the second compartment (tailing going to flotation) at two sizes: 7~2.5-mm., and 2.5-mm.~100-m. (*Q*). Jigs are of typical wooden construction, in pairs, back to back; bottom slope, 24°. Compartments are all of equal size, 26(wide)×34-in., with 1/4-in. steel-plate liners covering all wearing surfaces. Plungers are 31 9/16 × 25 1/8-in. Bed concentrates are drawn through side dam-and-gate valves 10 in. from discharge end, and join the hutch concentrates below. Brass-wire screens rest on grates of 3 1/2×3/4-in. wooden cross bars spaced 4 in. c-c.; life of screen, 120 days. Drop between screens, 5 1/2 in. Depth of bed, 3 1/2 in. Feed contains 29% water;

jig water, 84 g.p.m. Power, 3 hp. per jig. One man attends 8 jigs, but is responsible for no adjustments. Lost time (mainly for repairs), 4%. Additional data are in Table 3. Earlier practice in the Bunker Hill & Sullivan mill retains much of technical interest. Table 4 records the performance of jigs (as of 1925) working at 4 graduated screen sizes, the finest one deslimed; all jigs were 4-cell. Still earlier practice (about 1910) was chiefly interesting for its extended use of classifier jigs to treat the whole <10-mm. screen product without previous desliming; also for use of a hydraulic classifier to enrich the first and second hutch products of those jigs (*2 MM 361, 441*). The first cell of the 5-cell classifier jig had two sheet-iron partitions from side to side dipping about 1 in. into the bed; the first was near

the middle, lengthwise, and the second a few inches nearer the tailboard; both classifying compartments discharged over weirs at one side into the same spout. The slime, practically completely eliminated, was 17% >40-m. and 50% <200-m.; it amounted to 8.4% of the jig feed, and assayed 16.25% Pb. All cells of the jig had gate-and-dam discharges at middle of the tailboards. Hutch concentrates from the first two cells, consisting of high-grade coarse and low-grade fine grains, were delivered, after dewatering, to hydraulic classifiers made of steel pipe and fittings but based on the design of the glass laboratory classifier shown in Sec. 19, Fig. 106. Falling products of these classifiers were high-grade concentrates; the rising products were treated on shaking tables. Table 5 gives operating data on jigs formerly treating complex lead-zinc ores at U. S. SMELTING, REFINING & MINING Co., Midvale plant; all jigs were 3-cell, about 23 1/2 × 35 1/2 in. BLEISCHARLEY mill, in Upper Silesia, affords modern example of closely graded crushing and jigging (*112 A 952*). Ore is dolomite carrying replacements and fracture fillings of wurtzite, galena, marcasite, and GALMEI (mixed silicate and carbonate of zinc). Average assay, in 1931, was: Zn, 19% (of which 1.7% was in oxidized minerals); Pb, 2.8%; Fe, 6%. Each of three sections, treating 300 tons in 8 hr., has 15 trommels, making 10 undersizes, and 3 hydraulic classifiers subdividing the undersize from the finest trommel. Each section has 19 jigs treating the sizes shown in Table 6. In a typical month, the jigs rejected 21% of the mill feed as tailing assaying. 2% Zn, 0.10% Pb, 4.4% Fe; their lead concentrates assayed 4.5% Zn, 71.4% Pb, 4.8% Fe. Practically all of the zinc products of the jigs required ball-milling and flotation for elimination of iron. Harz-type jigs until recently have been practically the sole mechanical separators for the TSCHIATURI, Caucasus, manganese ores, operating usually on short-range feeds, *e.g.*, 30~20, 20~15, 15~8, 8~5, 5~3, and < 3-mm., obtained from shaking screens (*34 ME 619*). The ores contain both extremely hard and excessively soft and friable minerals; concentrates up to the standard 52% grade were seldom possible, and losses of Mn were 40% or more, chiefly in slimes. There was no provision for retreatment of middlings. In one modern mill of 50-t.p.h. capacity, erected in 1935, only 2 sizes, 40~22 mm. and 22~8 mm., produced on submerged-screen washers, are treated on 3-cell Harz jigs (one for the coarser, two for the finer size), yielding finished concentrates, final tailings, and a middling product which, after recrushing to 8-mm., rejoins the undersize from the 8-mm. screen washer for treatment on Hancock-type jigs (see Art. 10). The first 2 cells of each jig deliver concentrate; middling from the third. Data in Table 7 are on the hourly basis; analyses are averages from a 3-day test run. Of the total feed to the mill, averaging 38.77% Mn, the Harz jig concentrates (both sizes) amounted to 21.5% by weight, and accounted for 28.7% of the Mn (other recoveries by movable-sieve jigs and tables); their tailings amounted to 5.6% of the mill feed, and carried 1.7% of its Mn.

ABERFOYLE, Tasmania, tin-tungsten mill offers a good example of stage jigging of short-range feeds; capacity, 50 tons per 8 hr. (*30 CEMR 303*). Ore averages 1.5% Sn, 0.2% WO_3, in fairly coarse cassiterite and wolframite crystals not intimately intergrown with the other metallic minerals, hematite, pyrite, and other sulphides. Jigging begins at 3/8-in. (following jaw crusher and rolls); undersize of the finest trommel, 1/16-in., is classified through 1 spigot for a jig, and 3 spigots for tables. Jigs are bedded with soft-steel punchings, 1/8- to 5/8-in.; speeds, 140 r.p.m. on coarsest, 220 r.p.m. on finest jig. Of the total mill feed, 4 primary jigs treat 88.7%, collect 1.82% in concentrate, reject 84.5% in tailings, and deliver 2.34% as middlings. A mill test gave the data in Table 8 for primary jigs only. Combined jig and table concentrates, averaging 56% Sn, 6.5% WO_3, are separated magnetically. Combined middlings (10.9% Sn, 1.3% WO_3, 12% Fe, 4% Cu, 7% Zn, 0.5% As, 25% S) are roasted, roll-crushed through 1/8-in., and sized at 1/16-in., making feed for two 2-compartment jigs. Recovery in the whole operation is 87%; ratio of concentration 43.5 : 1. Harz jigs on MALAYAN TIN DREDGES (*52 MM 244*), treating gravel in which most of the cassiterite is finer than 10-m., usually have 4 hutches

48 in. long; screen, 42 in. wide; piston compartment, 36 in. wide; bottom slope, 38°; depth of longitudinal partition below screen, 15 in. for fine, 10 1/2 in. for coarser jigs. Drop between screens, 2 to 3 in. for unsized feed, 1 in. for close work on sized feeds; tailboards, 4 in. high on roughing, 3 in. on cleaning jigs. Jigs with screens set at uniform slope from feed to discharge end have been used, aiming to increase capacity, but are more difficult to adjust and control. Pistons are of 2-in. board, reinforced at both ends by 2×1/4-in. iron straps, top and bottom, and having an A-shaped iron bracket for rigid attachment of piston rod. If loose-fitting, clearance is 3/8 to 5/8 in.; if tight-fitting, the piston is provided with downward-opening clack valves; a 36×48-in. piston may have 14 such valves, each with 4-in. square opening, distributed as in Fig. 39. Too much suction produces a low-grade hutch concentrate. Usual screen is 1/16-in. sheet with slotted holes 1/2 to 5/8 in. long by 1/8 in. wide for roughing, or 1/16 in. for cleaning jig; long dimension of slot is crosswise of the flow. Screen is reinforced above and below by identical iron grids with webs 3 in. deep; grid above the screen provides pockets for maintaining the bed. Most satisfactory bedding is crushed hematite, sized at 3/8- to 1/2-in. for roughing, or about 1/4-in. for cleaning jig; usual depth, 3 in. Rubber, or rubber-lined hutch discharge spigots are satisfactory. Speeds for average feed are 140 to 160 @ 3/8-in. s.p.m. for roughing jigs; 160 to 180 @ 3/16-in. s.p.m. for cleaners. Water for a 4-cell jig with above dimensions, 640 g.p.m. for all purposes. Feed to such a jig should not exceed 20,000 cyd. per mo. A correctly operated jig may lose less than 1% of the tin in the gravel, and makes satisfactory recovery of cassiterite as fine as 0.25 mm. Slope of launder for transferring rougher concentrates to cleaning jigs is about 1 : 6 unless additional launder water is supplied. If dewatering is required, a spitzkasten of at least 8-cu.ft. capacity should be installed ahead of each cleaner. Of 119 tin dredges working in Malaya in 1931, 62 employed jigs, and 57 sluices only (*30 ME 217*); the largest at that time had 14-cu.ft. buckets, could dig at 130-ft. depth, and treat 326,750 cyd. per mo. A dredge might have 10 to 16 roughing, and 1 to 3 cleaning jigs, the latter making a concentrate with 25 to 50% Sn which was enriched to 72% Sn by further treatment on shore. At the Djebel-Trozza mines, 2 Standard (Harz-type) jigs, with combined screen area of 6.4 sq. meters, treat 9 metric tons per hr. (140 kg. per sq. dcm.) of an ore averaging 3.5 to 4% Pb in form of galena and cerussite in a gangue of quartz, shale, and granitic rocks, affording an easy separation (*8 Rev. de l'Ind. Minerale, pt. 1, 158*). Two jigging sizes,

1~5- and 5~15-mm., are made on a single vibrating screen. Jig screens (62 cm. wide) are perforated sheet with 7-mm. holes for the coarse, and 3.5-mm. for the fine, jig. Piston of the coarse jig makes 130 @ 35-mm. s.p.m.; of the fine jig, 155 @ 25-mm. s.p.m. Water, 320 liters per min.; power, 16 hp. The jigs discharge about 50% of clean tailing; concentrate assays 61% Pb. In reconstruction of the mill, these 2 jigs replaced 5 coarse and 9 fine ordinary Harz jigs, with combined screen area of 16.2 sq. meters, which previously had treated only 7 t.p.h., after close sizing on 5 vibrating screens, and with consumption of 1,120 liters of water per min. The new arrangement employed 6 fewer men and saved 0.70 franc per ton in wages. CIA. DE MINAS DE COLQUIRI, Bolivia, uses 4-compartment Harz jigs for initial treatment of its complex tin ore; sole purpose of the jigs is to discard tailing. Mine ore averages 3% Sn, 26% SiO_2, 22% Al_2O_3, with sulphides of Fe, Pb, Zn, Cu, Sb, and Ag. Removal of 65 tons of hand-picked waste leaves 525 t.p.d., averaging 3.88% Sn, to be treated by the jigs at 3 sizes. All compartments are 18 × 32 in., fitted with steel-plate screens having 4-mm. round holes; life, about 30 days. Each jig takes 3 hp. Additional data are in Table 9. In the pyrite section of its Chaupi mill, CIA. DEL CERRO DE POTOSÍ, Bolivia, treating a complex tin ore, uses two 4-compartment Harz coarse jigs (in parallel with one 3-compartment Bendelari, Art. 7), and one 2-compartment Harz fine jig, all locally constructed. Purpose of the coarse jigs, immediately following primary crushing and screening, is to discard largest economic amount of tailing and produce a rough pyrite-cassiterite hutch concentrate for recrushing; that of the fine jig, treating original fines, is to extract a fairly clean pyrite concentrate and thus relieve the work of tables cleaning fine jig tailing. All Harz jigs have 24×36-in. screens of iron sheet punched with square holes; life 30 days. Bedding is 1/2-in. pyrite, 3 in. deep. Table 10 gives screen analyses of feeds; operating data in Table 11. Middlings from the fourth compartments of the coarse jigs return to the head of the jig without further reduction.

4. COOLEY JIG

Description. This is a variant of the Harz type used extensively in the Mid-Continent zinc fields. Its only essential difference from the ordinary Harz jig is that it is almost always used to make hutch only and no screen discharge is provided, except sometimes for middlings. Coarse concentrate and middling are shoveled off intermittently as operation demands. Attempts to run with continuous draw of rich bed concentrate result in hard beds, with impaired jigging action, and the discharge of a large amount of low-grade material. If the amount of coarse concentrate and middling is large, it is usual, in the case of the middling at least, to use a coarse screen and jig through an artificial bed, using long stroke, low speed, shallow bed and high drop between screens.

Construction. The usual method of construction is cheap and highly efficient. The floor is built up of 3 layers of 1-in. T-and-G boards laid in white lead or asphalt paint and nailed flat; walls and partitions are 2×4-in. studs, dressed, laid flat and nailed, with two strips of cotton wicking, saturated with white lead, laid between. The front of the hutch is stepped out 8 to 10 in., then carried up straight. The walls of the plunger compartment are carried up to give support to the journal boxes and to prevent splashing. The entire jig is lined with 1-in. boards and these are also used to form a sloping bottom for the hutch. The usual sizes of screen compartments are from 20 to 42 in. wide by 24 to 48 in. long with 6- to 9-in. tailboards on the first compartment ranging down to 5- or 6-in. on the last. Practice as to depth of bed varies. A deep bed requires much water, which sends fine free mineral to the later cells. These are made hard by the swift flow of excess top water and as a result the fine mineral goes into the tailing. Excess top water in the tail end of the jig may be eliminated by breaking the jig in two and dewatering before the last cells. A common drop in the 30×36-in. size is 1 3/4 in.; in a 42×48-in. jig at the MEDIA MILL, a 3-in. drop was used. Punched-plate screens are common. The sieves are sloped downward toward the tailing end, as much as 1 in. in their length, in order to compensate for the greater weight of concentrate at the head end and prevent uneven water distribution.

Number of compartments. Jigs used to make clean concentrate and tailing on 3/8-in. or 5/8-in. screen undersize (one-jig mills) are 7- to 9-compartment. In such a jig, cell No. 1 is used for clean

lead concentrate, cell No. 2 makes a lead-zinc middling that is either circulated or reground; cells 3 to 5 produce clean zinc concentrate and, in a 9-cell jig, cells 6 and 7 are also used to make clean zinc; the last two cells produce middling for regrinding. The greater number of cells is used for high-grade feeds or with ores containing much lead; in the latter case cell No. 3 may also make middling and cell No. 4 may be the first zinc cell. Single-jig treatment is suitable only for low-grade, coarsely disseminated ores low in lead. If there is much lead it will appear in the zinc concentrate. With the 2-jig arrangement the combined hutch products of the first or rougher jig carrying 10 to 25% zinc, locally called SMITTEM, are sent to the cleaner; tailing is discarded. Some, but very little, blende finer than 200-m. is caught on these jigs and about 30% of the zinc in the tailing is this fine material. Finished concentrate, assaying 75 to 80% lead, is taken from the first hutch of the cleaner, the second hutch is sent back to the head of the cleaner, hutches 3 to 6 are clean zinc concentrate assaying 50 to 60% zinc, and hutch 7 is returned to the head of the cleaner or reground, depending upon whether the values are free or locked mineral. The latter material is locally called CHAT and assays from 4 to 8% zinc. The cleaner tailing is either thrown away or sent to a sand jig of 3 to 5 cells, usually of smaller grate area than the cleaners.

Operation. Rougher jigs are run at 90 to 125 @ 5/8- to as much as 2 1/2-in. s.p.m.; cleaners at 160 to 200 @ 3/8- to 3/4-in. strokes, and sand jigs at 150 to 190 @ 1/8- to 1/2-in. strokes. Some mills use special CHAT JIGS of 4 to 5 cells run at higher speed and shorter stroke than the cleaner jigs. Typical adjustments are shown in Table 12. In some cases the drive shaft is in two sections and the head end is driven at 20 to 30 r.p.m. less than the tail end. All jigs are run with strong suction, which is enhanced by leaving the hutch gates partly open. To make rich lead concentrate requires high-grade feed. There is an advantage in sending the first rougher-jig hutch to a small separate jig; otherwise it is necessary to build up the grade of the cleaner feed by circulation of the lead concentrate. Water consumption ranges from 800 to 1,200 g.p.m. for a 7- to 9-cell jig. A common figure for estimate is 1,500 to 2,500 g.p.t. treated. The capacity of a rougher is from 8 to 12 tons per sq. ft. of screen surface per 24 hr.; for a cleaner 3 to 4; for a single-jig mill, 4 to 5 tons.

Performance. In the Tri-State field in 1934 *(112 A 861)* the Cooley jig served 3 purposes: (*a*) Roughing into low-grade concentrate, middling, and tailing for discard; (*b*) cleaning rough concentrate; (*c*) treating the recrushed middling from the rougher and tailing from the cleaning jig, discarding its tailing and returning its rough concentrate and middling for further treatment.

Roughing jigs receive deslimed roll product, commonly <1/2-in., containing 2 or 3% <65-m. (Tables 13, 14). Usual roughing jig has 6 cells in series, 42(wide)×48-in., with 3-in. drop. Piston compartment is 4 in. wider than the screen. Throat (see Fig. 35) is about 2/3 width of screen; depth of partition, 0.4 width of screen. Minimum bottom slopes (PITCH) in last cell, 34°; in others pitch boards are set to maintain the same throat in all cells. Tailboards are 6 to 8 in. high. Water usually enters above piston. Screens normally range from 1/4-in. in the first to 1/8-in. in the last two or three compartments. Speed, 90 to 120 @ 1- to 2-in. s.p.m.; variations within these limits are compensated by stroke and piston water to maintain suitable bed conditions. A 6-cell @ 42×48-in. jig treats 25 to 30 t.p.h. Rough concentrate from the first 4 cells, amounting to 15 to 30% of the jig feed, assaying 25 to 30% Zn, and accounting for 80 to 85% of the values fed, passes directly to the cleaning jig. Of free mineral in the feed, 95% is recovered here with no particular difficulty. Screen concentrate from the first 4 compartments is removed by hand and joins the corresponding hutch products. Frequent and rather drastic hammering is required to keep the screen apertures open. Middling from the last 2 cells, amounting to 5 to 10% of the feed, assaying 4 to 8% Zn, and accounting for 5 to 10% of the values, is recrushed and rejigged. Concentrate on these two screens is usually drawn continuously; the most

satisfactory draw (CHATTER) is a 2-in. pipe with 3/4-in. slots spaced 4 in., which is set horizontally across the screen close to the tailboard; extra water may be supplied at the inner end to assist discharge. The relatively low sp. gr. of the middling and the large volume of jig water over the last 2 cells make it difficult to separate clean tailing. Rougher-jig tailing represents 60 to 80% of the feed, assays 0.75 to 1.00% Zn in a well-regulated mill and considerably higher in others, and contains 10 to 15% of the values; it is deslimed and dewatered before discard. Grade of tailing made is governed by the amount of middling removed and the retreatment cost, and is varied with the market for zinc concentrate.

Table 13. Performance of Cooley roughing jig, Tri-State District

Total.............	100.0	7.53	100.00	1.15

Cleaning jig receives combined rough concentrate as above after desliming. It resembles the roughing jig, but usually has 7 @ 36×42- or ×48-in. cells with 1.5-in. drop; speed, 160 to 165 s.p.m.; stroke length ranges from 1 3/4 in. on the first to 3/4 in. on the last cell; screen apertures as in Table 15. The first cell (and sometimes the second) makes finished lead concentrate; the next, a mixed Pb-Zn concentrate which returns to head of the jig; the remaining cells yield finished zinc concentrate, except that the product of the last cell is sometimes returned to head of the jig. A sufficient depth of natural bedding is maintained to insure clean hutch products. Excess bedding is removed by hand,

by dam and gate, by chatter (see above), or by PIN DRAWS, which are 3/4-in. round iron bars fitting holes punched in the screen, and are withdrawn at intervals to discharge into the hutch. Tailing joins roughing-jig middling. Lead concentrate assays 79 to 84% Pb, 1.5 to 2.5% Zn; zinc concentrate, 57 to 62% Zn, 1 to 1.5% Pb; sized as in Table 15.

Chat-roughing (or CHAT-SLOUGHING) jig is one of several means employed for retreating rougher middling and cleaner tailing. These products combined are recrushed (usually by rolls) to <1/8- or 3/16-in. and deslimed. The jig usually has 5 cells, 36×42-in. to 42×48-in., with 1.5- to 3-in. drop. Speed, 160 to 180 @ 1- to 0.75-in. s.p.m. Screens are either fine with natural bedding, or coarse and bedded with screen concentrate from the rougher; excess bed is drawn in same way as from the cleaning jig. Product of first 2 cells returns to the cleaning jig; middling from remaining cells, enriched to about twice the value of the feed, is further treated on tables or by flotation; tailing, amounting to 50 to 60% of the feed to the jig (about 5% of mill feed), and assaying 1.5 to 2% Zn, is discarded. If original middling is crushed to 2- to 2.5-mm. the jig (then called a SAND-CLEANER) may make clean zinc concentrate from two or more hutches, and tailing may be further treated. Table 16 gives the performance of such a jig working on 2.5-mm. deslimed feed.

Jig practice would probably be improved by roughing for clean mineral only (on a shorter jig), dewatering rougher tailing, scavenging for two grades of middling, combining the high-grade with cleaner tailing, and crushing the low-grade to 28-m. for classifier-table treatment.

Recent practice indicates that initial roughing by sink-float is superior to rough jigging from both metallurgical and cost standpoints. See Art. 30, and Sec. 2, Fig. 117.

In the WISCONSIN DISTRICT (*111 J 1065*) the average recovery from 1.75% Zn feed is 55 to 60% in a 48% concentrate; tailing averages about 0.6% Zn, of which the part >10-m. runs about 0.4% Zn, the >40-m. 0.95%, and slime, 8%. On 6% feed through 3/8 in., jig mills in this district make 65 to 70% recovery in a 45 to 50% concentrate carrying less than 3% CaO; about 75 to 80% of the concentrate is >20-m. AMERICAN ZINC Co., at Mascot, Tenn. (dolomite-sphalerite ore), made coarse concentrate on a 6-cell roughing and 7-cell cleaning jig, recrushing all tailings for flotation. Feed to the roughing jig was nearly all <3/8-in., 19% >1/4-in., 42.2% >8-m., and 38.4% <8-m.; it averaged 3.8% Zn and carried 37% of water (Q). Screen compartments were 32 (wide) × 48-in. on the rougher, 28 × 42-in. on the cleaner. Screens, 14-gage steel plate with slots respectively 1 × 3/16 in. and 1 × 1/8 in.; life, 92 days. Beds, 8 to 10 in. deep. The rougher treated 600 tons per 24 hr.; water, 460 g.p.m.; power, 18 hp. Speed, both 110 r.p.m. Length of stroke, rougher, 1 5/8 in. in the first two, 1 1/2 in. in the next two, and 1 3/8 in. in the last two compartments; cleaner, 5/8 in. on the first, 1/2 in. on the next four, and 3/8 in. on the last two compartments. One man attended 2 jigs, making all adjustments except speed; substantially no time was lost. For present practice see Art. 30, and Sec. 2, Fig. 102.

a 36 × 42 in. Speed, 164 s.p.m.

As employed on some MALAYAN TIN DREDGES in 1929 (*39 IMM 180*) Cooley roughing jigs had 3 or (preferably) 4 completely separated cells usually 3 ft. wide by 4 ft. long; on clean-up jigs, treating hutch product of the roughers, 4 cells were desirable. Screens on both jigs were most commonly of sheet steel with punched slots 1/2 × 1/8 in.; crimped wire screen, with same aperture and of about 0.11-in. wire, was equally serviceable and gave more open space. Screens were not in horizontal steps, but had a continuous slope of 1 : 16 for full length of jig. Preferred bedding was hard hematite, crushed to 3/4- to 3/16-in., rounded by a preliminary tumbling for about 2 hr. in a 4-ft. revolving drum, and rescreened over 1/8-in.; bedding for the clean-up jigs was sized through 3/8-in. screen. Hematite beds were about 2 1/2 in. deep, maintained by cross bars in the holding-down frame; weight, about 34 lb. of prepared material per sq. ft. of screen. Jig beds of sized, coarse cassiterite proved unsatisfactory. Speed of roughing jigs was usually 110 r.p.m. (faster when heavily loaded); of clean-up jigs, 190 r.p.m.; length of stroke was then adjusted to correct performance at those speeds.

5. MAY DUPLEX JIG

May duplex jig (*44 Aa 225; 72 Aa 113; 88 Aa 247*) has been universally adopted for coarse concentration (followed by tabling and flotation) of lead-zinc-silver ores in the Broken Hill district, N.S.W. It consists substantially of two identical and parallel jigs, back to back, wholly independent except as to their driving mechanism, of rocker-arm type, operated by a common shaft. Number of compartments in series ranges from 3 to 5; the last compartment, without screen or plunger, occupies the full width of the jig and serves to collect tailing and to regulate, through a float valve, the flow of wash water to the jig. Dimensions and operating data at 5 mills active in 1928 are given in Table 17.

a Lengthwise of the jig, and including idle compartment at tailing end; complete jig has twice as many compartments.

b 5 in. below screen at central position; power consumption, 0.83 hp. per piston.

c Tons per hr. per duplex jig: Feed, 13.2, of which, 75% through 4-mm. rd., and 25% through 4.2-mm. sq. hole; all deslimed; concentrate, 0.9 to 1.0; middling, 1.1; tailing, 11.2.

d Not deslimed.

Products are drawn exclusively through the hutch. Screen rests on a cast-iron grid, and is covered by a similar grid, cast in soft brass, with webs about 2 in. deep, forming pockets to retain the bedding, which consists usually of short cylindrical pieces cut from round iron rod. Feed is roll product, screened through 3- to 4.2-mm. holes, and deslimed in drag classifiers of Esperanza type.

In the Broken Hill South mill, in 1931, with 2 (active) compartments, the first delivered a finished galena concentrate; the second, a Pb-Zn middling which was reclassified and returned to the jig (without intermediate crushing); tailing, carrying all of the blende except that unavoidably caught in the lead concentrate, was recrushed for tabling and flotation. Data on these products are given in Table 18. In some of the other mills, all of the active compartments deliver galena concentrate, all mixed grains being thrown into the tailing for retreatment. The typical gangue minerals of the district are calcite, rhodonite, garnets, feldspars, fluorspar, and quartz. Sulphides other than galena and blende include pyrite and pyrrhotite, with minor amounts of arsenopyrite and chalcopyrite. Galena is relatively coarse throughout the district.

6. OTHER PLUNGER JIGS FOR ORES

Collom jig has a special plunger mechanism which gives a quick downward stroke and retarded return. The mechanism has link-operated rocking hammers striking the plunger rods down sharply against the pressure of springs which lift the plungers more slowly. The plungers may be fitted more tightly than the eccentric-driven type, because of their non-rocking travel, but the mechanism is more complicated and less rugged than the

b Returned to jig without further crushing.
c Recrushed for tabling and flotation.

simple eccentric. The jig is built double with sieve compartments outside of the plunger compartments; these are about half the area of the sieve compartments and are placed side by side, each occupying one-half the length of the jig. This causes maximum water effect at the feed end of one compartment, which is not distinctly harmful, and at the tailing end of the other compartment, which is harmful. Distribution of water is partly equalized by a horizontal partition below each plunger, of which the quarter nearest center of its corresponding screen compartment is open for passage of water.

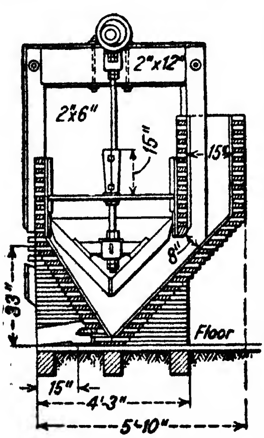

Fig. 7. Dee jig.

Dee jig (Fig. 7) has a hopper-shaped valved plunger under the screen with the plunger rod passing through the center of the screen. The valved plunger decreases suction and gives uniform distribution of water currents, but at the expense of great inconvenience in operation and maintenance. The cribbed construction is also found in jigs of the Harz type.

Hodge jig is of the Harz type but has a mechanism for attaining differential plunger motion. It has been used to a considerable extent in the Lake Superior copper mills. It is built in cast-iron double units which are set up in pyramid arrangement.

Performance. At Copper Range mills four double Hodge jigs with 24×36-in. compartments are used in series. They are fitted with double-crimped brass-wire screens of the following sizes: 8-m. No. 18 wire on No. 1 (life, 324 days); 10-mesh, No. 20 wire on No. 2 (life, 405 days); 12-mesh, No. 21 wire on No. 3 (life, 260 days); 14-m. No. 22 wire on No. 4 (life, 260 days). Speed of all jigs, 165 s.p.m., @ 7/8-, 3/4-, 5/8- and 1/2-in. respectively, with 2.75- to 3-in. beds. Capacities: First sieve, 21 tons per 24 hr.; second, 16; third, 9; fourth, 6. Water consumption ranges from 160 g.p.m. on No. 1 to 100 g.p.m. on No. 4. Power consumption, 0.52 hp. per sieve. Feed contains 80 to 85% water. Assays: Tailing, 0.5%; concentrate, 65% Cu.

New Century jig is usually equipped with a differential motion giving accelerated down stroke to the plunger with corresponding accentuation of pulsion. Suction is decreased

by a rubber flap-valve around the plunger edge which closes on the down stroke and opens wide on the return. Differential motion is produced by raising the plunger against a spring by means of a cam lifting against a roller, the plunger being forced down quickly by the spring when the cam releases.

Performance. Notable installation was that of New Jersey Zinc Co., separating closely sized willemite and zincite from a calcareous gangue, on 32 @ 6-compartment jigs with 24×36-in. sieves. Data concerning the installation at Franklin Furnace, N. J., are shown in Table 19. One man attended 4 machines. Lost time was 10 to 15%, which is exceptionally high, the principal cause being repairs. 5 hp. was consumed per jig. For present methods in this mill, see Art. 7.

Shields and Thielmann jig (Fig. 8) was used at the Quincy mill for treating unclassified native-copper ore through 5/8-in. grates from steam stamps. The unit is a 4-compartment cast-iron jig tank, 12 (wide)×24- to 30-in., each hutch connected by a 4-in. pipe through the side wall with a vertical cylinder in which runs a piston, eccentrically operated from a common shaft. Eccentrics are individually adjustable and each hutch is fed by a separate water supply. Both gate and hutch discharge are provided.

A 4-section installation at the Quincy mill treated 500 tons per 24 hr. Power consumption was between 3 and 4 hp. for the 16 compartments. The vertical screen between the sections caused size grading in successive discharges. Coarse copper, 3/8-in. to 5/8-in., discharged from gates 1 to 3. Clean concentrate was also taken from hutches 1 and 2. Gates 4 and 5 discharged coarse middling. Gates 6, 7 and 8 were kept closed to accumulate concentrate; gates 9 and 10 discharged middling for regrinding. The remaining sections discharged middling products of various sizes from 1/8-in. to 40-m. and of various grades from both gates and hutches. Slime (<40-m.) overflowed from the last compartment.

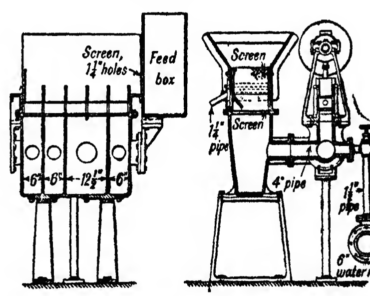

Fig. 8. Shields and Thielmann jig.

Woodbury jig (Fig. 9) is a quick-return plunger jig, the plunger having a smaller area than the sieve. Two plunger rods with separate eccentrics are used on each plunger. The jig is made in units that are erected end-to-end at different levels (pyramid setting), the feed entering over an apron above the plunger compartment. The jig is best known by reason of a slime-separating device on the first unit of a series treating ungraded feed. This consists of a shield *a*, which projects above the water level and dips sufficiently into the sand layer on the screen to prevent slime from entering at the bottom. Slime is thus diverted around the shield and overflows a dam at the discharge side of the compartment. This same dam serves to hold back sand tailing, which rises within shield *a* and overflows lip *b*. A concentrate cup *c*, within shield *a*, projects above the sand level and down into the concentrate layer on the screen, therefore allowing concentrate only to enter and overflow into pipe *d*. This pipe is connected with pressure water to allow fine sand to be excluded from the cup concentrate by classification. Deslimed sand tailing (middling) passes to a second unit fitted with the usual gate-and-dam concentrate discharge placed,

however, at the tailing-discharge end of the compartment. When further units are used a dewatering trough is placed ahead of each subsequent unit and a similar device on the tailing-discharge box of the final unit.

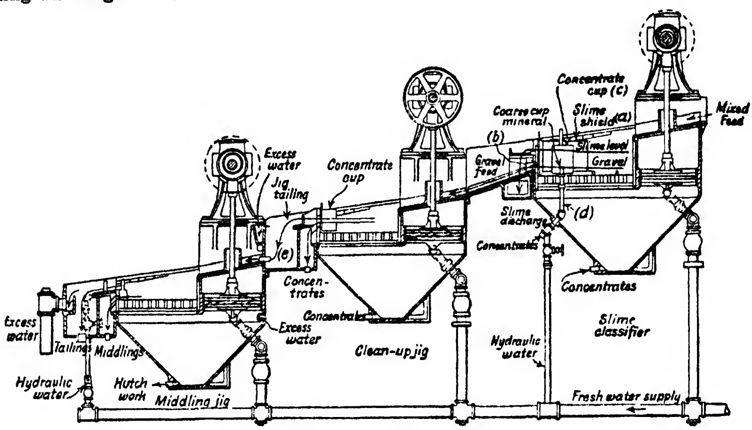

FIG. 9. Three-unit Woodbury jig.

Performances. At CALUMET & HECLA CONGLOMERATE MILL, in each of the 11 crushing units, two 4-cell jigs treat screen discharge from one steam stamp, or 150 tons per day for each jig. Sizing assay of feed, as in 1929 (*IC 6364*), is given in Table 20. Some coarse copper is removed by a mortar jig (*Ed. 1, p. 319*) without having to pass the 3/16-in. screen. The first compartment is 26 in. wide; of its length, 16 in. forms the plunger, and 35 in. the screen compartment. The other three tanks are 50 in. wide, each having a 16-in. plunger and a 30-in. screen compartment. Actual plunger dimensions, allowing for liners and clearance, are 14 3/4 × 24 in. for the first, and 14 1/2 × 48 in. for the other three compartments. Screens are of brass wire, 8-m. on the first two, 10-m. on the last two compartments, supported on wooden cross bars 3 in. deep and 2 in. apart. At customary speed of 195 r.p.m., strokes are 7/8-in. for the first, 3/4-in. for the second, and 5/8-in. for the other two compartments. Jig beds, 2 1/2 in. deep. Each screen compartment (after the first) has two dam-and-gate discharges for coarse concentrate, spaced 1 ft. each side of the centerline. As operated in 1929, on feed diluted with about 4 parts of water, by weight, the jig delivered 4 products: (*a*) Slime, all <60-m. and 93% <200-m., which was thickened for flotation; (*b*) hutchwork, through 10-m. jig screens, direct to Wilfley tables; (*c*) copper concentrate, from first 2 cells only, averaging 89.4% Cu and constituting 41% of the total gravity concentrate (56% from tables); (*d*) coarse and fine sands, all recrushed, together with table middling, for tabling and flotation.

Table 20. Woodbury jig feed (1929), Calumet & Hecla Conglomerate mill

65	6.1	2.2			

At the FREDA MILL of Copper Range Consolidated Co., a single-cell Woodbury jig extracts coarse copper, 90–92% Cu, from the product of a short-head Symons crusher set at 1/4-in. opening. Screen analysis of the jig feed (38% solids) is given in Table 21. Average assay of feed, 7.7% Cu; feed rate, 425 tons per 24 hr. Jig screen, 47 1/2 × 29 1/2 in., is sheet steel, 3/16-in. round holes; life about 400 @ 12-hr. days. Bed is 4 in. deep. Speed, 160 @ 2 1/2-in. s.p.m. Motor, 3 hp. Tailing, 1.0% Cu.

Table 21. Screen analysis of feed to Woodbury jig, Freda Mill

14	0.2	200	0.6
20	0.2	<200	1.7
28	0.1		100.0

At ANACONDA the Woodbury system was thoroughly tried but not adopted; Table 22 gives data on this test. When treating deslimed undersize of a 4-m. screen, a classifier jig and three retreatment jigs in series produced, from 127 tons per 24 hr. of feed containing 0.82% Cu, 15.5 tons of middling (concentrate) at 2.43%, 6.8 tons hydraulic middling assaying 1.14%, slime assaying 3.4%, and tailing assaying 0.45%. At OHIO BRASS Co. (*65 A 652*) a 2-compartment jig, first compartment 12 × 21 in. with 10-m. screen and 1 3/8-in. stroke, the second 18 × 24 in. with 6-m. screen and 3/4-in. stroke, 200 r.p.m., treated brass-foundry ashes sized between 3- and 10-m. on heavy-wire stationary screens set at 45°. Cup concentrate was almost pure metal (70 to 80% Cu) and represented 60 to

70% of the total metal in the feed; hutch concentrate assayed 65 to 70% Cu and contained about 20% of the total copper fed.

A diminutive type of single-cell Woodbury jig, without classifier or cup-discharge attachments, is available for installing in tube-mill grinding circuits; sulphides and coarse gold are extracted as a hutch concentrate. Standard sizes are 12×12- and 18×24-in.; the smaller jig will treat 25 to 50 tons per day of new feed, plus circulating loads up to 400%. Wendigo Gold Mines reports extraction of 80 to 95% of its recoverable gold by such a jig.

McLanahan-Stone jig has been widely applied to low-grade Lake Superior iron ores. Fig. 10 illustrates a 4-cell design employed at two manganese-ore plants in Tennessee (*IC 7145*). Distinguishing features are the circular, cast-iron plunger and the feeding of each cell with ore of a different size; in effect, the installation consists of 4 separate 1-cell jigs consolidated for convenience in construction and operation. Feed, sized on the sectionalized trommel *A*, falls immediately into the rear end of the sieve compartment, the screen of which (supported by cast-iron grid) is slightly inclined toward the discharge end. (Other methods of sizing the feed are employed elsewhere.) Mesh of the jig screen is fine

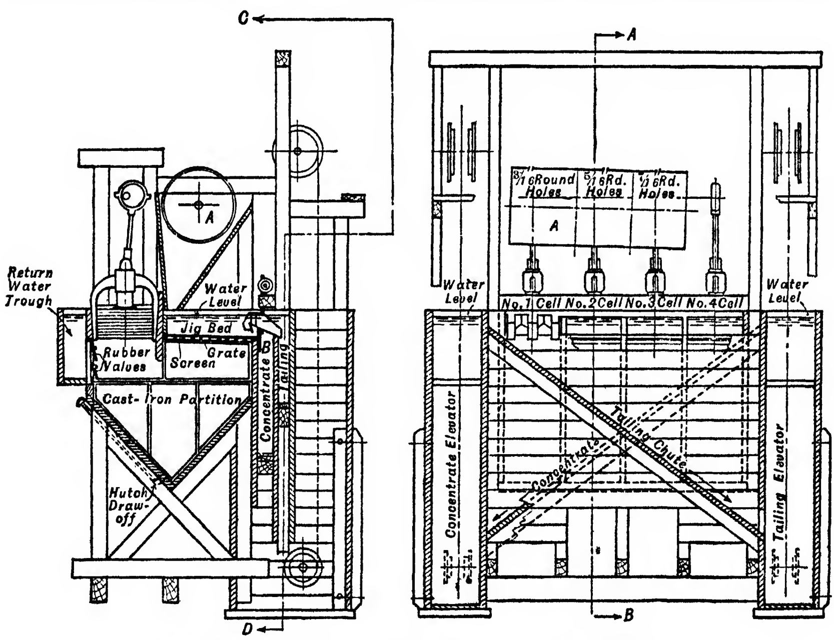

Fig. 10. McLanahan-Stone jig.

enough to retain substantially all ore in the feed; hutch product is only incidental. The entire width of the discharge end of each cell is occupied by 2 adjustable gate-and-dam discharges for concentrate, and 3 spouts for tailing, the latter bridging the narrow concentrate receptacle *B* and delivering to a similar and parallel receptacle. The bottoms of these receptacles slope in opposite directions, whereby the concentrates descend to the foot of an elevator at one end of the jig, and the tailing similarly at the other. Both elevators have perforated buckets for draining products. Water stands at the same level in all compartments, collecting receptacles, and elevators; an open trough returns water from the concentrate elevator to the rear of the jig, whence the water enters the plunger compartments through clack valves, 2 or 3 for each cell; this arrangement accents the pulsion stroke and also economizes water.

Performance. EMBREE IRON CO. used a jig with four 48×27-in. cells to complete the enrichment of hand-sorted, log-washer concentrate of a nodular psilomelane ore <3/4-in. size, at the rate of 10 long tons per hr. of operating time, and consumed 18 hp.; water, 200 g.p.m. Adjustments are given in Table 23. EAST TENNESSEE MANGANESE CO. uses a similar jig on similar ore, treating the <5/8-in. fraction of concentrate from a log washer. Jig speed, 83 r.p.m.; other adjustments as in Table 23.

Bull jigs are of any type, but usually fixed-sieve, used for treating the coarsest feeds. Heavy ores up to 3-in. diameter have been treated. Bull jigs differ from others of the same type only in that they are built heavier to withstand the longer stroke and greater wear, and discharge ports must be larger to prevent clogging. In a Joplin bull jig with 36×60-in. sieve compartments, two eccentrics are used on each plunger.

Performance. At BUNKER HILL AND SULLIVAN (*61 A 225*) bull jigs formerly treated 1 1/4~1/2-in. material to make middling and tailing only. This method saved the heavy wear on soft galena concentrate that results if it is attempted to make a high-grade concentrate. The best grade that could

a Slime overflow, 10 in.

be made on these jigs was 55% lead and that wore the concentrate into rounded marbles. But by taking a 25% rough concentrate, crushing it, and re-jigging, a 65% concentrate was made with but little wear on the galena. These jigs handled 150 tons per 24 hr. and rejected 90 tons of tailing containing less than 0.4% lead. At SLOCAN, B. C., bull jigs made a lead concentrate as coarse as 3/4-in. (*114 J 677*.) Table 24 gives data on a competitive test between a Woodbury bull or DE-WOODING JIG and the Harz bull-jig system at ANACONDA.

Neill jig (Fig. 11). Water currents are produced by a swinging vertical paddle, actuated by a rocker arm. Hutch concentrate only is made and is discharged continuously through three 3/8-in. spigots from each hutch. The jig was developed for service on gold dredges and was the forerunner of other simpler and more compact types now extensively utilized in that field. On the NATOMAS No. 7 dredge (*101 J 207*) the jig screens were 2 ft. 5 in. by 3 ft. 8 in., 8-m. Monel metal, bedded 1 in. deep with BB cast-steel shot. Each jig this size consumed 2.6 hp. at 172 r.p.m. Gold in the jig concentrate all passed 20-m. and 43% passed 100-m. Jig concentrate contained 6 to 7% of all the gold caught on the dredge. This was ground in a conical mill and treated in a shaking amalgamator and on plates.

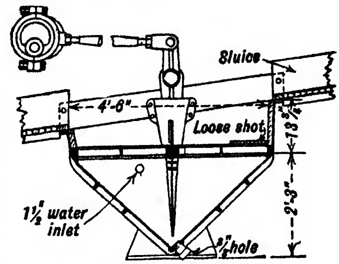

FIG. 11. Neill jig.

7. DIAPHRAGM JIGS

Bendelari jig (Fig. 12) pulsates water by means of the diaphragm *A*, having a flexible margin *B*, actuated vertically by the constrained piston rod *C*, which is driven, through a wrist-pin joint, from the simple eccentric *D*. The air well *E* eliminates glands and stuffing boxes. Corners of the plate *F*, supporting outer edge of the diaphragm, are cut away to make space for the fall of hutchwork. The upper edges of the webs of the grid *G* supporting the screen are champfered and cut away between the corners of each opening, so that the screen actually rests only at web intersections, which increases the effective screen area. Slotted steel sheet is the most usual screen material for the coarser feeds. Water enters through clack valve *H;* adjustment of the valve *J* regulates the relative pulsion and suction effects in the bed. When producing only hutchwork, screen is commonly bedded with steel shot. If coarse product also is desired, the jig may be equipped with screen discharge of dam-and-gate or other suitable type; Fig. 12 shows a perforated-pipe chatter *K*, similar to that on Cooley jigs in the Tri-State field.

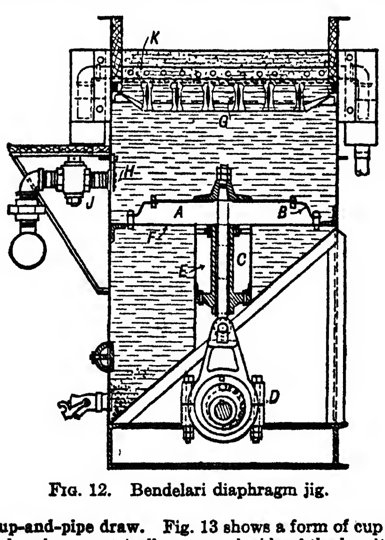

FIG. 12. Bendelari diaphragm jig.

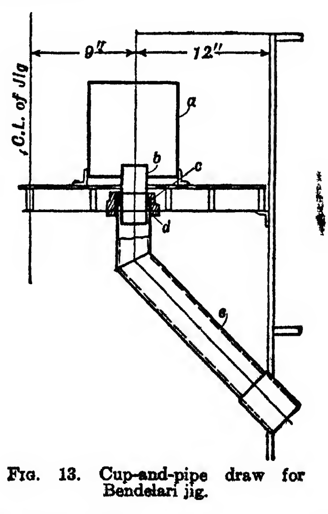

FIG. 13. Cup-and-pipe draw for Bendelari jig.

Cup-and-pipe draw. Fig. 13 shows a form of cup drawoff used on a 42×42-in. compartment. Two are placed symmetrically, one each side of the longitudinal centerline of the screen 12 in. from the tailboard. A 2 1/2-in. discharge pipe *e* on 45° slope, runs from each through the front wall of the jig. Cup *a* is a piece of 8-in. pipe supported on angle feet as shown, or better from a small truss running across the top of the compartment. The dam *b* is a piece of 2-in. pipe held in a rubber ring *c* set into 2 1/2-in. pipe cap *d*, thus being readily adjustable in height.

Performance. Structural and operating data at a few mill installations are in Table 25. ARGONAUT MINING Co., Jackson, Calif., introduced a 2-cell jig between ball mill and classifier to scalp out pyrite and coarse gold from the grinding circuit preceding flotation; gold thus recovered has a higher net value per ounce than that contained in flotation concentrate shipped to a smelter. Hutch product of the jig is retreated on a quarter-size Wilfley table yielding gold (for amalgamation), sulphide concentrate, and tailing (returned to classifier). The jig is cleaned thoroughly, and again partially, at ends of alternate weeks; thorough cleaning requires a 5-hr. shutdown; incomplete, less than 1 hr. For a thorough cleaning, loaded screen is removed and replaced by one freshly bedded, and hutch is washed down. Contents of screen are sieved on 4-m., picking out nuggets and returning oversize ore to ball mill. Undersize is re-sieved on 8-m., and steel shot is removed by magnet. The <8-m. goes to amalgamating barrel together with gold recovered on the table. For a partial clean-up, only the head end of the jig is rebedded, without moving the screen. Shot consumption, 400 lb. per yr. Beds are rabbled once every hour. Hutch water is seldom adjusted except as required by changes in rate of feed; stroke is gradually lengthened from 7/16 to 1 in. as pyrite bedding accumulates; tightness of bed is avoided. Table 26 summarizes recoveries from Jan. 1, 1937, to Sept. 1, 1939. (A mine fire suspended operations for 5 mos. of 1938.) (*PC* from E. M. Smith and A. F. Ross.) At SUMMITVILLE CONSOL. MINES a single-cell Bendelari jig (data in Table 25) is used for extracting pyrite and coarse gold from an all-cyanide grinding circuit. Desideratum is jig tailing that can be cyanided efficiently. In 10 mo. the jig produced 101 tons of concentrate, assaying 6.27 oz. Au, from 35,500 tons of feed containing 0.312 oz. Au per ton; jig concentrate thus amounted to 0.28% of mill feed, and contained 5.8% of its gold (*PC*). KELOWNA EXPLORATION Co., at Hedley, B. C., has a single-cell jig (data in Table 25) in a pebble mill-classifier circuit primarily to remove pyrrhotite from a basic ore in which chalcopyrite carries most of the gold, and associated arsenopyrite must be crushed to 325-m. for satisfactory cyanide extraction; overcrushed pyrrhotite retards settling and filtering, and increases cyanide consumption. At MINERA POTOSÍ, Bolivia, in the pyrite section of the Chaupi mill, a 42×42-in., 3-compartment Bendelari jig operates in parallel with two 4-compartment Harz jigs; feed is identical with that to the coarse Harz jig in Tables 10, 11, Art. 3. The Bendelari treats 350 met. tons per day, against 300 tons by the two Harz jigs, with the same metallurgical efficiency. Screens are iron sheet, punched with 6-mm. square holes, and last 30 days; bedding is 3 in. of 1/2-in. pyrite. Speed,

Total	94.3	95.9	95.4

160 r.p.m.; strokes, 1 1/4-in. on the first, 1 1/8-in. on the second, 1-in. on the third compartment; motor, 7-hp. Bendelari has a more open bed; larger capacity, consumes less water and power; and requires less maintenance.

Low California-type Bendelari is specially adapted for dredges; it is built in units of 1 to 4 cross-flow cells. The standard 42-in. roughing cell treats 15 cyd. per hr. of gravel $<1/4$- or 3/8-in. Slotted 3/32-in. screen, and 5/32-in. shot are common, coarser sizes occasional. Concentrates from 6 to 8 roughing cells are usually delivered to a single-cell cleaning jig, normally having 1/16-in. slotted screen and 7/64-in. steel shot. Ratio of concentration on roughers varies widely, but is usually 20 to 25 : 1; ratio on the cleaner, 6 or 8 : 1.

Substitution of jigs for sluices, as now quite widely practiced, has almost invariably shown improved recovery, especially on dragline dredges where restricted deck room compels short sluices (*PC*). See also Sec. 2, Art. 21. Much of the earlier difficulty with jigs on gold dredges was due to blinding of screens by accretions of amalgam, the jigs then commonly being used as scavengers of sluice tailing; in recent practice, this objection has been met by installing jigs ahead of sluices, or by omitting mercury on any sluices preceding the jigs.

Performance on dredges. Jasper-Stacy Co. uses 2 double-cell roughers and a single-cell cleaner to supplement riffle sluices on a dragline dredge treating about 2,000 tons of trommel undersize in 20 hr. running time per day (data in Table 27); the jigs account for about 25% of total recovery. One man attends all 5 cells. Malay States Tin, Ltd., installed 14 roughers and 2 cleaners (all of 4 cells each)

on a 13 1/2-cu. ft. dredge treating 400,000 cyd. per month; mixture of sand and clay carried 0.1 to 1.3 lb. of cassiterite per cyd., with max. 0.25 lb. of pyrite and variable amounts of other minerals of 5 to 6 sp.gr. (data in Table 27). Feed varied with nature of ground from 8 to 20 cyd. per hr. per jig. Occasional overloading, in sandy ground, caused maximum delay of 30 min. per day; normal repairs were made weekly. A foreman and 5 men per shift attended to all jigs.

Pan-American Placer jig has been used principally as primary concentrator on gold dredges, treating the undersize of 3/8- to 1/2-in. dredge screen, and delivering hutchwork only, containing free gold mixed with a large proportion of other heavy minerals. For such work, the jig most often has two identical cells, 42×42-in., in tandem (end flow) or parallel (cross flow); smaller sizes, 12-, 26-, and 36-in., are used as cleaning jigs, though the pulsator jig (below) is usually preferred for this service. Each cell may be operated with its own pulsating mechanism (standard drive), or 2 cells may be operated, through walking beam, from the same eccentric (balanced drive); Fig. 14 illustrates the latter type. The square compartment *A* has an open conical bottom *B*, the lower edge of which is joined, by the circumferential rubber strip *C*, to the upper edge of

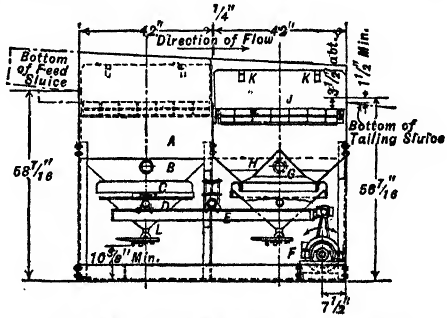

Fig. 14. Pan-American balanced Placer jig.

the conical hutch *D*. This entire lower portion of the cell is supported and vertically reciprocated by the balanced beam *E* (or by an individual vertical eccentric rod, in the standard type), actuated by the eccentric *F*. The beam may be oscillated from either end of the jig and the shaft rotated in either direction. Hutch water enters continuously at *G*, and is distributed by passing under conical baffle *H*. The screen, commonly of woven wire with 0.083×0.475-in. apertures, is assembled with its upper and lower grids in form of a basket *J*, which may be removed and replaced as a unit, lifting by hooks *K*. A 42×42-in. cell requires a minimum of 425 lb. of steel shot, commonly $^3/_{16}$-in. Hutchwork discharges continuously through an adjustable, rubber-lined gate *L*; owing to the oscillation, a relatively small orifice can be used without clogging. (In the standard jig, the hutch discharges through a spout to one side.) At the most favorable dilution for primary feed, 4 to 6 : 1 by volume, a 42×42-in. cell should treat about 25 cyd. of gravel per hr. and consume 100 gal. of hutch water per min.; usual speed, 120 to 130 s.p.m., and stroke, $^3/_4$ to 1 $^1/_2$ in.; running power for each cell of a balanced jig, about 0.5 hp., but a 2-cell jig is usually equipped with a 2-hp. motor. A standard jig of the same size requires a 2.5-hp. motor for each cell. The standard one-cell jig is built in 12-, 26-, 36-, and 42-in. sizes and has been used in grinding-classifier circuits in gold mills; in this service, it should not be required to treat more than 250 (dry) tons per day per sq. ft., including circulating load, requiring 3 to 6 gal. of water per min. per sq. ft. Usual speed, 150 to 180 @ $^1/_4$ to $^3/_4$-in. s.p.m.

Performance. Table 28 gives data on two installations of the one-cell placer jig in gold-milling circuits, additional recoveries being made by other methods. On dragline dredge on JORDAN CREEK, Idaho (*139 #7 J 60*), conventional sluices were replaced with Pan American jigs, Placer type for gravel and pulsating type for cleaning rough concentrate; also a small Placer jig for scavenging tailing from the cleaner, and a small pulsator for scavenging discharge from an amalgamator. The eight 42×42-in. cells of the primary jigs were in two blocks of four on opposite sides of the screen, and so arranged that each of the 4 cells next to the distributor passed its tailing to a second cell; the leading cells caught about 80% of the total concentrate. Each block was driven by 5-hp. geared motor, but required only 2 hp. while running. Excess power was for difficult starting in freezing weather. Speed, 120 @ 1 $^3/_4$-in. s.p.m. Capacity per cell, 30 cyd. per hr. of gravel, mostly <$^3/_8$-in. and all <$^1/_2$-in. round-hole. Gravel contained about 8 volumes of water; additional jig water was about 80 g.p.m. per cell. Hutch spigot, $^7/_{16}$-in. Cleaning jig (Crangle pulsator, Art. 8) had two 12×12-in. cells, rated at $^1/_2$ to $^3/_4$ cyd. solids per hr. Bedding, $^1/_4$ to $^3/_{16}$-in. shot. Speed, 200 s.p.m.; water, 10 to 20 g.p.m. Concentrate passed through an amalgamator and thence to a single-cell, 12×12-in. pulsator jig. Tailing from the cleaner jig was scavenged on a placer jig with four 9×9-in. cells in series, bedded with $^1/_4$- to $^3/_{16}$-in. shot and coarse concentrate, largely garnets. Speed, 240 s.p.m.; water, 15 g.p.m. to each cell. Stroke averaged about 1 in.; shortest at the head end.

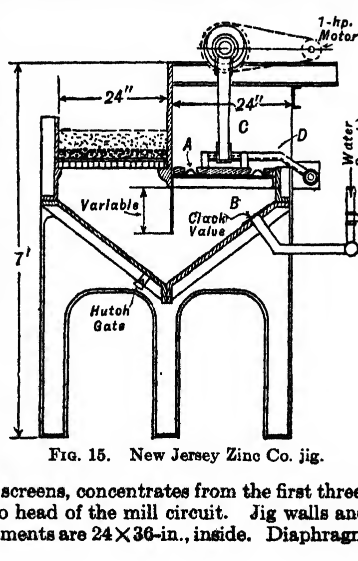

FIG. 15. New Jersey Zinc Co. jig.

New Jersey Zinc jig (Fig. 15) has been substituted for the New Century jig (Art. 6) at Franklin Furnace (Sec. 2, Fig. 106). Very short-range feeds of willemite, zincite, and calcite are concentrated. All jigs have 4 compartments, yielding products exclusively through the bedded screens, concentrates from the first three, middling from the fourth; the middlings return to head of the mill circuit. Jig walls and underpinning are in cast-iron segments. Compartments are 24×36-in., inside. Diaphragm

A comprises a central solid part and a flexible sheet surrounding it with the edges sealed at walls. The diaphragm is actuated through connecting rod *C* from a simple eccentric; a 1-hp. variable-speed motor drives 4 compartments. The vertically swinging arm *D* counteracts any tendency toward lateral motion. Screens are of woven brass wire, with apertures as in Table 29, about twice the size of the largest grains in the feed. They are supported on grids which rest on flanges cast in the wall and partition plates of the jig. Elevations of the screens are such as to maintain ore beds with the depths stated in Table 29, and with uniform drops of 1 in.

Permanent bedding consists of clean franklinite (sp. gr., 5.1), crushed, sized between 0.1- and 0.5-in., and tumbled wet to round the sharp corners; it is then rescreened closely, and each jig is bedded with material averaging twice the diameter of the screen apertures, or about 4 1/2 times that of the ore (see Table 29). This avoids blinding screens. Bedding lost by attrition is replaced at intervals of about 3 weeks; entire bed is removed and resized twice a year. One operator attends to 5 jigs, adjusting only the speed and the hutch water as may be required by variations in richness of feed. This enters the jig through clack valve *B* from a vertical, tubular, hydraulic classifier which washes fine dry dust from the feed as received from the screens. At Mill A, feed averages 22% Zn; concentrate, 47%; tailing, 1.2%. At Mill B, feed is 17%; concentrate, 48%; tailing, 1.8%; middling (to tables), 10% Zn.

Denver Mineral jig (Fig. 16) is specially designed for closed grinding circuits, taking feed directly from the mill and recovering hutch concentrate only. It comprises the typical divided box with top-driven diaphragm *a* one side and screen the other. Eccentric drive is direct in single-compartment types and by walking beam *b* in 2-compartment machines. Hutch water enters through a rotating valve *c*, driven by sprocket chain from the eccentric shaft, and so set as to admit water only during the suction stroke. Entire screen assembly, consisting of a lower wedge-wire screen, a bedding of steel shot, and an upper and coarser ordinary screen for catching refuse, is removable. Simplex jig is made only in the 8×12-in. size. Duplex jig has 2 end-flow screen compartments, from 8×12- to 24×36-in. for 7 to 1,000 tons new feed per 24 hr. to grinding circuit. Stroke is adjustable up to 3/4-in.; usual speed, 300 s.p.m.

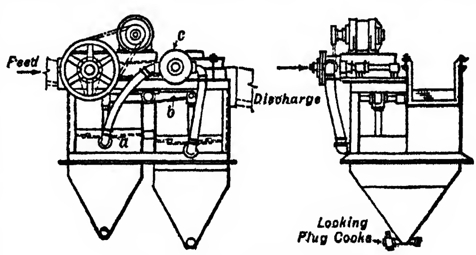

Fig. 16. Denver Mineral jig.

Performance. At Paymaster Consol., in 1939, two 16×24-in. duplex jigs in parallel treated daily about 540 tons of mill discharge averaging (with considerable fluctuation) 50% <200-m. and 0.27 oz. Au; density, 68% solids. Jig tailing carried 55% solids, showing addition of 0.35 ton of solution per (dry) ton of feed. The jigs delivered 12.8 tons of concentrate per day (ratio, 42.4 : 1) averaging 2.61 oz. Au. Hutch concentrate was drawn continuously through pinchcocks and delivered to a thickener; between leaving the jigs and discharging from the thickener, concentrate yielded gold to solution amounting to 27% of that in the primary mill feed. One of the jigs was equipped with a separate admission valve for each hutch, permitting individual control. Each jig was driven by 1.5-hp. motor, drawing 0.5 hp.; 320 @ 3/8-in. s.p.m. Screen had 2-mm. openings. Life of a bed, 6 weeks to 6 mo.,

averaging 3 1/2 mo. Bed was changed, by removing entire screen box and substituting another previously prepared, whenever it would no longer draw freely without discharging slime with the concentrate; changing took 2 men about 1 1/2 hr. Old bedding was washed free from slime and screened at 1/4-in.; oversize returned to mill; undersize, freed of small steel fragments by magnet, was used for a fresh bed. To form a bed, the cleaned screen was covered with 20 lb. of new 1/8-in. steel shot, and 45 lb. of screened bedding (or of clean pyrite, in case of a new jig); this made a bed about 1.5 in. deep, which increased to 3 in. after operating a short time.

Southwestern-Kraut Hydromotor jig has a square screen between lower and upper grids *a*, Fig. 17, latter being held in position by the side liners *b* and setscrews *c*. The square hutch *d*, flexibly connected to the bottom of the jig box by the rubber flange *e*, is supported and vertically oscillated by spider arms attached to the lower end of a central shaft *f*. Near its upper end, this shaft passes through a housing *g*, within which, and fixed to the shaft, is the pulsator motor, consisting essentially of a piston *h* and a rubber disk *i*. The motor may be driven by either air or water, at 8- to 10-lb. pressure; in the latter case, motor discharge water may enter the hutch through the pipe *j*, or flow to waste through the outlet *k*, under valve control. The screen is bedded with steel shot. Speed and character of stroke are varied by adjusting pressure on the spring *l*, which carries the whole weight of moving parts. Sizes range from 12×12- to 42×42-in.

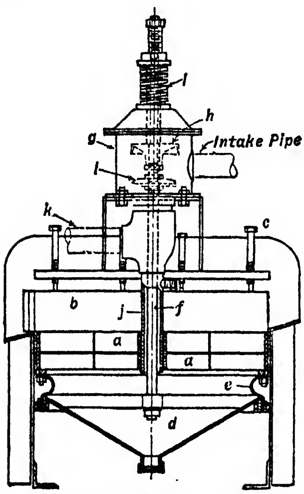

FIG. 17. Southwestern-Kraut Hydromotor jig.

Performance. At the NORTH STAR 500-ton mill, Grass Valley, Calif., a 42-in. jig treats the <3/8-in. discharge from 20 stamps, returning tailing to a closed grinding circuit for flotation (*PC*). Table 30 gives typical results during the first year's operation. At the 250-ton mill of CENTRAL EUREKA MINING CO., Sutter Creek, Calif., a 42-in. jig in closed circuit with ball mill and classifier, recovers about 75% of the total gold and returns tailing to the classifier. Rich hutch concentrate is amalgamated in a 5-stamp battery, the residue from which assays about the same as flotation concentrate and is shipped with it. At THREE R MINES, near Nogales, Ariz., three 36-in. Kraut jigs as roughers and one 24-in. as cleaner constitute the entire treatment of copper ore reduced to <3/16-in. by jaw crusher and rolls. These jigs are equipped for both screen and hutch discharge of concentrate.

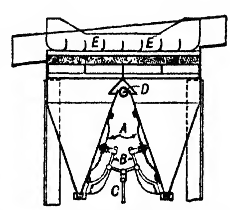

FIG. 18. Titan twin-diaphragm jig.

Titan twin-diaphragm jig (Fig. 18) uses a bedded screen and delivers hutchwork only. It has a double-hoppered hutch surmounted by a single screen. Diaphragms *A* are actuated simultaneously through the knuckle arms *B* and the pitman *C*, by an eccentric. The eccentric shaft has also a crank-and-rod connection with a valve controlling admission of water through the inlet *D;* valve is closed during the pulsion stroke; adjustment of the valve gear allows positive control of suction. Diaphragm stroke is adjustable between 1 and 2 1/2 in. Baffle plates *E* are assembled in a removable frame. Bedding (usually 3/16- to 1/4-in. steel shot) is held in place by a grid with rectangular openings corresponding with those in the supporting grid. Standard widths are 16 to 42 in.; lengths, 29 to 60 in. Capacity on average ore or gravel is claimed to be 40 to 50 tons per sq. ft. per day.

Ruoss jig (Fig. 19), introduced on MALAYAN tin dredges, has four consecutive hutches, each 4(wide) $\times$ 3 $^1/_2$-ft., covered over their entire area by steel sheet *F* punched, usually, with $^1/_2 \times ^1/_8$-in. slots, and resting on a cast-iron grid. The screen may be horizontal, but usually slopes 9 $^3/_4$ in. in total length of 14 ft. The partition *H* between the second and third hutches is completely stationary; the other two partitions are perforated with the largest possible (40-in. diam.) circular openings, which spaces are occupied by the diaphragms *D*, connected to the partitions by flexible, annular bands *J*. The diaphragms are hollow and water-tight, thus providing enough buoyancy to support their own weight and that of the connecting rod *C;* the latter of 2-in. I.D. steel tube in short sections with sleeve connections for convenience of installation, and welded to the diaphragms. Connecting rod and diaphragms are oscillated longitudinally by an eccentric and yoke mechanism *E*,

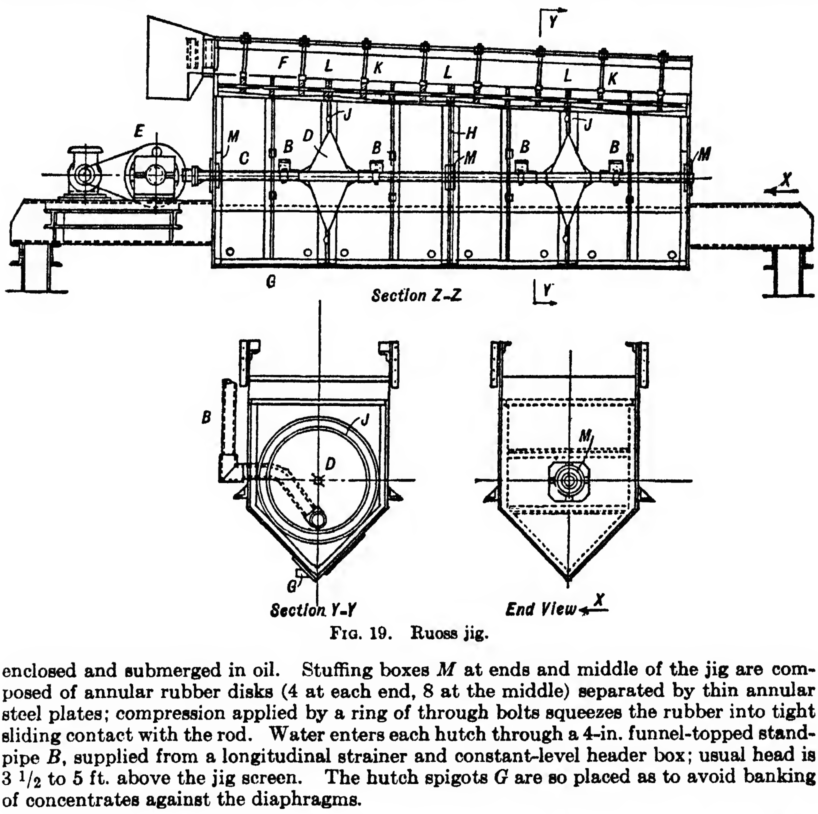

FIG. 19. Ruoss jig.

enclosed and submerged in oil. Stuffing boxes *M* at ends and middle of the jig are composed of annular rubber disks (4 at each end, 8 at the middle) separated by thin annular steel plates; compression applied by a ring of through bolts squeezes the rubber into tight sliding contact with the rod. Water enters each hutch through a 4-in. funnel-topped standpipe *B*, supplied from a longitudinal strainer and constant-level header box; usual head is 3 $^1/_2$ to 5 ft. above the jig screen. The hutch spigots *G* are so placed as to avoid banking of concentrates against the diaphragms.

Permanent bedding, of $^1/_2$- to $^3/_4$-in. hematite, is about 3 in. deep, and is kept in place by a welded-steel grid with 6 $^1/_2$-in. spaces; the grid is held immovable by the strut bolts *K*. Usual depth of sand, maintained by the dams *L*, is about 4 in. The standard 4 $\times$ 14-ft. jig weighs about 3 tons, and costs (made in MALAYA, 1939, and including royalty) about £220. Speed, 130 s.p.m. on roughers, 180 s.p.m. on cleaner jigs. Stroke, $^1/_4$-in. usually, $^3/_4$-in. maximum. Motor, $^3/_4$-hp. Minimum water, 5 g.p.m. per sq. ft.; usual provision is 360 to 400 g.p.m. for a standard 4-hutch jig. Water-supply pump is usually specified for a total head of 40 ft. Capacity per sq. ft. of screen is about the same as that of a Harz jig, but total capacity is about twice that of a Harz of corresponding over-all size, which is important on a dredge. Average for several Ruoss installations is 0.5 cyd. per sq. ft. per hr. One dredge with six 6 $\times$ 16-ft. jigs has treated 200,000 cyd. per mo., with tailing loss of 0.015 lb. cassiterite per cyd.

8. PULSATOR JIGS

Richards pulsator jig (Fig. 20) was the forerunner of the present-day pulsators. It consisted essentially of a compartmented jigging tank, with a fixed screen, underneath which water was fed through a rotating valve. Concentrate discharged from the screen

through the usual gate and dam. When operated with closed hutch the bed was subjected to pulsion impulses only and kept remarkably loose. Speed for such jigging was about 200 s.p.m. Jigging with sized feeds was very rapid and the tonnage per sq. ft. of screen area many times that of a plunger jig. If suction was desired, the speed was lowered to 150 to 175 s.p.m. and the hutch gate opened. Owing to the fact that an 8- to 10-in. bed could be maintained and owing also to the relatively light suction, very clean concentrate was made. Power consumption was much less than for plunger jigs. Water consumption was high.

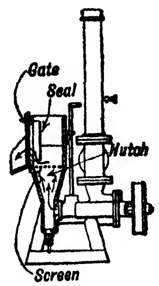

FIG. 20. Richards pulsator jig.

The jig did not respond readily to changes in tonnage and richness of feed, probably on account of the small size of the cells, yet it was limited to small cells to keep down water consumption. It was not satisfactory for hutch-making service, but was best suited to treatment of closely sized ores with large differences in specific gravity between mineral and gangue, and where low-grade tailing was not essential. In such service it delivered a high-grade concentrate with small power and not excessive water consumption. At ANACONDA a No. 2 jig treated material sized between 8 and 2.5 mm. in a short test at the rate of 224 tons per 24 hr. and made concentrate assaying 9.8% Cu and tailing about 2.2% from a feed containing 2.85%. This result compared unfavorably on a metallurgical basis with the work of the Hancock, Harz, and Woodbury jigs at these plants.

Pan-American pulsator jig has been chiefly employed for cleaning the rough concentrate from primary jigs on gold dredges (also as roughing jig in small-scale work), and in closed grinding circuits in gold mills, but for such use the amount of water added through the jig may prove undesirable. The jig requires no power, except to provide a 5- to 10-lb. head of water; this may be excessively dirty. Fig. 21 is a cross-section, showing a typical form of shot-bedded screen *A*, supported by a grid *B*, while a similar grid *C* holds the screen in place and provides pockets for retaining the bed of shot. In Fig. 22, *E* is the valve seat, and *D* a rubber diaphragm to which the seat is attached. Upward motion due to pressure of water entering at *A*, and rendered possible by the predominating area of the diaphragm, is resisted by spring *B*, which closes the valve when upward pressure is momentarily diminished by escape of water into the jig, through *F*. Rate of pulsation, 400 to 600 per min., is adjustable by varying the compression on the spring. Standard sizes

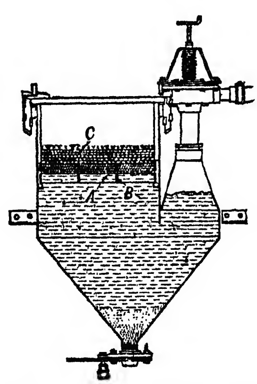

FIG. 21. Pan-American pulsator jig.

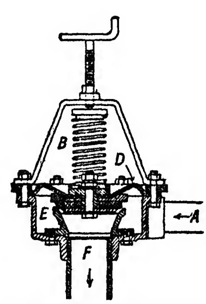

FIG. 22. Valve of Pan-American pulsator jig.

are 12×12-, 18×18-, and 24×24-in. A single cell usually suffices in a closed grinding circuit; for open circuits, or when used as a cleaner, two cells are advisable. Feed should not exceed $^1/_2$-in. size, and $<^1/_4$-in. is desirable, because the large amount of water required to maintain suitable activity in a coarser bed adversely affects the recovery of fine mineral in absence of suction. When used on a dredge for cleaning rough concentrate, 1 sq. ft. of screen is claimed to treat the hutchwork from four 42-in. roughers on average gravel; feed dilution, preferably not over 2 : 1 by weight, which usually involves some dewatering; jig water, 12 to 16 g.p.m. per sq. ft. As a roughing jig, capacity is 1.5 to 2.5 cyd. per hr. per sq. ft., at a dilution preferably not over 3 : 1 by weight; greater dilution is permissible, but reduces capacity. In closed mill circuits, capacity is 200 to 250 tons total per sq. ft. per day; preferred dilution, 55 to 70% solids; jig water, 10 to 14 g.p.m. per sq. ft.

Performance. Table 31 gives data on two small installations of pulsator jigs used as roughers, working on drift-mine placer gravel. Table 32 gives three examples of installation in closed grinding circuits in gold mills. At AUBURN, CALIF., the jig is between the ball mill and a Deister table in closed circuit with a classifier. Previously, the table alone had been making a high-grade pyrite concentrate and a bulky middling, together accounting for recovery (*via* amalgamation) of 63% of the gold in the circuit. On introducing the jig, recovery as amalgam increased to 77% of the total, and the table no longer yielded a bulky middling. Tests on the adjustments of the jig gave the data in Table 33; shot bed (equal parts of 3/16- and 1/4-in.) was 5/8 in. deep; results of the last test indicated that the jig was then recovering 79% of the gold and 85% of the pyrite in the ore. In the DAYTON, NEV., mill, only 5% of the total gold is freed in the ball-mill circuit; screen assay of jig concentrate, comprising pyrite, ruby silver, and free gold, gave the data in Table 34. ANGLO AMERICAN MINING CORP., Randsburg, Calif., introduced an 18-in. pulsator jig in the ball-mill circuit to treat 400 to 500 tons of total load per day; to maintain classifier pulp at 18% solids required least possible use of jig water. Ore ranged from 1 to 5% sulphides and free gold averaged 33% of total values. Purpose of the jig was to reduce total mill losses rather than make rich concentrate; by extracting coarse values (concentrate was nearly all >200-m.) mill recovery was increased by 0.01 to 0.02 oz. per ton, or more when the ore was high in talc. At MONTEZUMA APEX mine, Nashville, Calif. (*138 J 352*), a diminutive pulsator jig is used to recover free gold from the pyrite concentrate made by a unit-cell flotation machine, the latter treating <1/8-in. product in a closed grinding circuit, which also includes gold traps. Feed to the jig, about 1 ton per day, is about 90% pyrite, with a little gangue and some free gold not caught in the traps. The 12×12-in. jig has 1/16-in. punched screen, blocked off on all sides to leave an active area only 8 in. square. The 2-in. pulsator valve is 20 in. above jig bed and has a 10-ft. head; water connection to jig is 1/2-in. pipe. Bed of shot and 8~20-m. pyrite is 1 3/8 in. deep. Speed, 200 pulsations per min.; water, 3 to 4 g.p.m. Assay of feed, 8 to 9 oz. Au per ton; tailing, 2 to 4 oz. Clean pyrite assays 3 oz. Au, hence the jig appears to collect practically all of the free gold in the feed. Ratio of concentration, 15 to 20 : 1. Jig concentrate (together with gold from traps) goes to amalgamating barrel; tailing returns to the main flotation mill. Screen assay of concentrate, for *free* gold only, is in Table 35.

9. AIR-DRIVEN PULSATING JIGS

Baum jig (Fig. 23) is usually employed for coal washing. It has a fixed sieve *a* through which water is propelled by pressure of air (about 2 1/2 lb. per sq. in.) intermittently admitted through mechanically controlled valve *b* to a closed chamber *c* which is continuous with the chamber underlying the sieve compartment. Rate of change of air pressure in *c* is controllable through the setting of the valve mechanism, and almost instantaneous reversal in direction of flow with nearly constant acceleration to the end of stroke in both directions is said to be obtainable (*9 CE 204*). Screen discharge is from the front, actuated by the float mechanism *d;* light material overflows the end.

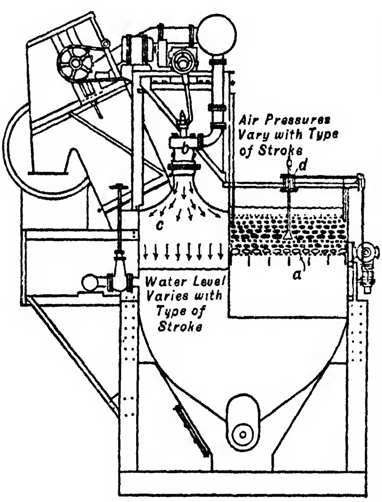

Fig. 23. Baum jig.

Conset (controlled-settling) jig causes rise and fall of water through a fixed screen by alternate inflation and deflation of rubber tubes (one for each hutch compartment) extending horizontally across the jig box close below the screen. Air at 2-lb. pressure, from a small compressor, is admitted and released through a header and mechanically operated valves, adjustment of which gives accurate control of pulsion and suction at speeds up to 350 pulsations per min. The screen is supported on a welded-steel grid, the outer edges of which rest on a rubber strip attached to the four walls of the jig box; when permanent bedding is desired, a similar grid is placed above the screen, covered, when necessary, by a coarse screen to exclude oversize material. There is no drop or partition between screens of consecutive compartments; ore may be made to travel in either direction by adjusting elevations of the two end boards. Concentrates are withdrawn in several ways, depending on their size and volume: (*a*) exclusively through the hutch, as when treating alluvial gravel or ball-mill discharge; (*b*) by skimming draws, discharging coarse concentrate into the hutch, from which it is extracted and dewatered by scraper elevator; (*c*) by a rotating star valve actuated by an adjustable-speed ratchet, receiving coarse concentrate through 2-in. slots crosswise of the screen and delivering it outside of jig box; (*d*) by ordinary gate-and-dam discharge, suitable for relatively small volumes of coarse concentrate but tending to interfere with stratification of thick beds. Water enters the hutch continuously through an inlet covered by a small baffle plate.

The Conset jig was developed and first used for Messabi low-grade iron ores. In most usual form for that service it

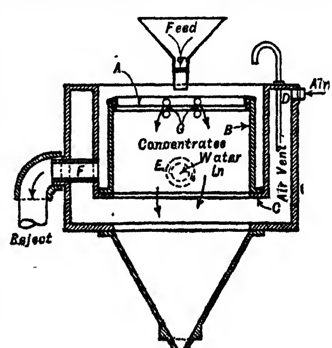

Fig. 24. Schiechel circular jig.

has 4 compartments, each 42 or 60 in. wide by 24 or 30 in. in direction of flow. A form designed for placer work has two 42×36-in. compartments, with minimum height of 61 in. to top of upper grid; a single-cell, 24×18-in. jig is also available. On iron ore crushed to <5/8-in., the jig treats 24 long tons per day per sq. ft. of screen, concentrate ranging up to 70% of the weight of feed.

Schiechel circular jig (SCHICKEL POT), developed from a laboratory jig designed by Büttenbach, is used in S. W. Africa for collecting alluvial diamonds which resist adhesion to the usual greased table (Sec. 12, Art. 17). The screen *A* (Fig. 24) rests on the upper edge of the circular bronze drum *B*, the latter supported by flanges on the inner edge of the cast-iron well *C*. Annular space around this well is closed at the top, making a chamber connected, through *D*, with a source of fluctuating air pressure (not a continuous supply). Water enters continuously at *E*, overflows the rim of the screen, and carries tailings to the discharge spout *F*. Feed comes on at the center. In addition to its ordinary apertures, the screen has holes *G*, large enough to pass concentrate, each closed by 2 wooden balls connected by a short piece of stiff wire. On the up-stroke, the upper ball lifts off the screen and allows some concentrate to fall into the conical hutch. Concentrate is withdrawn periodically at *H* and transferred to a cleaning jig, similarly operated, but without the holes *G*. From this jig the screen is lifted out at intervals and its contents are turned upside down on a sorting table; the diamonds are always found within a few inches of the center. (*38 Part 2 SAME J 181.*)

MOVABLE-SIEVE JIGS

10. HANCOCK JIG

Description. The principal parts of the apparatus (Fig. 25) are a compartmented tank *a*, movable sieve *b*, and sieve-actuating mechanism. Feed is introduced onto the screen at *d*, and caused to progress lengthwise by a series of grasshopper-like jumps induced by the sieve-frame motion. Concentrate works down through the sieve into the head-end hutch compartments, middling is drawn down into the later compartments under the screen, coarse tailing falls into compartment *e*, fine sand collects in *f*, and slime and excess

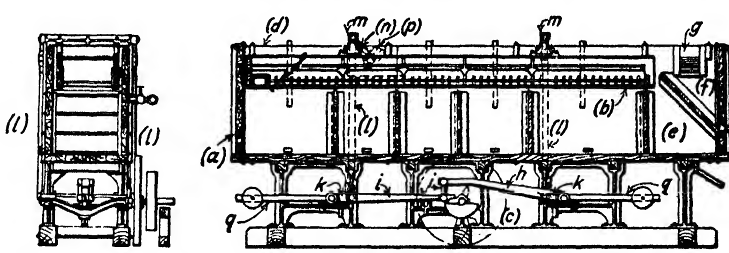

FIG. 25. Hancock jig.

water overflow at *g*. An extra, small compartment is often provided under a coarse screen between the last middling and the tailing compartments to catch any chance pieces of concentrate or middling too coarse to pass the screen or any piece of the ragging that may carry over. Two standard sizes of jig are made: the larger with a 6-compartment tank 25 ft. long, 4 ft. 2 in. wide, and 5 ft. 9 in. high; the smaller with a 5-compartment tank 18 ft. 6 in. × 4 ft. 5 in. × 5 ft. The sieve of the larger jig is about 20 ft. × 2 ft. 8 in. in the clear, when made of wood; when made of steel the screening surface is 20 ft. 4 in. × 3 ft. The actuating mechanism, usually placed below the tank but occasionally above to escape splash and grit, is driven by a cam shaft with a 3-armed cam *c*. The cam ears engage the end of lever *i*. Lever *i* actuates lever *h* through the link *j*, and the levers *i* and *h* actuate rocker arms *k* carrying 4 upright rods *l* connected in pairs at the top by cross bars *m* to which the sieve frame is attached. The head-end cross bar is linked at both ends to the jig tank by inclined radius links *n* adjustable as to their inclination with the horizontal by movement of the pivot pins in quadrants *p*. A considerable part of the weight of sieve frame and load is counterbalanced by the lever arms *q*. When lever *i* is raised by a cam ear, the sieve frame is raised by rods *l* and pulled forward by the radius links *n*; when the cam releases, the frame falls by gravity and at the same time is pushed backward by the radius links. The links work with an amount of lost motion controllable between 0 and 1/8 in. which produces a bump of greater or less intensity. The effect of the backward fall of the sieve frame and the bump combined is to cause forward travel of the material over the sieve frame, while the vertical motion produces the reciprocating water currents through the bed that cause stratification and separation of the minerals.

Construction. Complete jigs may be bought from various manufacturers, but usually only the iron work is purchased and the jig tank and supports and sieve frame are built on the ground. Wooden tanks are usual. They are built of 4-in. tongue-and-groove clear plank strongly stayed both vertically and horizontally at the compartment partitions. Partitions may be placed at any desired position, the best places being determined by experiment. They are usually so placed that the first concentrate and last middling compartment are considerably longer than the others. The sieve frame is made either of wood or steel. The wooden frame has four sides made of 2 $^1/_2$- or 3-in. × 18-in. plank, set on edge, and a grate *e* (Fig. 26) whose upper surface is about 6 in. above the bottom of the sides, for holding the screen. Top slats or battens *d* serve the double purpose of holding down the screen and of keeping the bed in place. One method of holding down the battens is shown in Fig. 26. Hardwood movable wedges *a* are driven between a fixed wedge *b* and a longitudinal bearing strip *c* placed against the side walls above the upper grid. The battens may be cambered about $^1/_8$ in. at the center. Packing strips *f* on the outside of the sieve frame and in a corresponding position on the inside of the tank prevent excessive displacement of water on the down stroke with consequent loss of pulsion. Steel sieve frames are built up with light-weight plate girders for side bars and suitably cross-braced. A sectional grate of 1×3-in. oak cross slats, iron-shod, with 2×3-in. oak rails is bolted in position in the frame (*93 J 1178*). Steel is lighter than wood, hence consumes less power, and gives greater screen area, which increases capacity. Bearing boards and hard-pine wedges are used to hold down the upper slats and screen. Hutch discharges are of many types. Two forms are shown in Fig. 27. Gates should be capable of reasonably close regulation and of quick wide opening. Considerable water economy may be effected by discharging coarse tailing with chain drag or shovel wheel. The water level is maintained about 3 to 4 in. above the surface of the solids on the screen or about 12 in. above the screen itself. It is controlled by slats placed in guides in the overflow weir, provided that the water supply is more than sufficient to satisfy any hutch draws. To prevent fluctuation in water level at the Leadwood mill of the St. Joseph Lead Co. a float in the tailing compartment controlled a butterfly valve in the feed-water pipe. A solid foundation of concrete or masonry is usually provided but the Doe Run Lead Co. placed a 25-ft. jig on a steel trestle 18 ft. high with no serious resulting vibration. At Rosiclare, Ill., the box itself rests on concrete walls instead of the usual cast-iron legs.

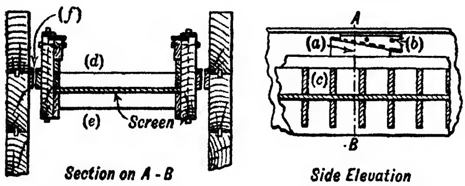

Fig. 26. Wooden sieve frame for Hancock jig.

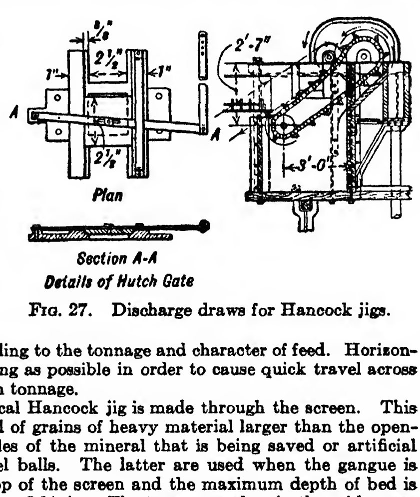

Fig. 27. Discharge draws for Hancock jigs.

Operation. The usual speed range is 180 to 195 s.p.m. corresponding to 60 to 65 revolutions of the drive shaft; a higher speed will increase tonnage but is very hard on the mechanism; at lower speeds the bed tends to pack. The length of the vertical stroke together with the amount of hutch water provided determines strength of pulsion and suction. The usual length is $^3/_8$ to $^3/_4$ in. With a long stroke more hutch product is made and the operator varies this adjustment according to the tonnage and character of feed. Horizontal throw is usually about $^3/_4$-in. It should be as long as possible in order to cause quick travel across the bed and thus maintain a thinner bed for a given tonnage.

All of the concentrate and middling from a typical Hancock jig is made through the screen. This necessitates the maintenance on the screen of a bed of grains of heavy material larger than the openings in the jig sieve. This may be coarser particles of the mineral that is being saved or artificial grains such as steel-plate punchings or iron or steel balls. The latter are used when the gangue is heavy. The bed is held in place by the grid on top of the screen and the maximum depth of bed is determined by the depth of the grid slats, usually 3 to 3 $^1/_2$ in. The transverse slats in the grid correspond with the supporting slats and are spaced 3 to 6 in. in the clear. Frequently longitudinal slats are also used in order to permit close control of the thickness of the bed at different points. At Anaconda, brass castings forming pockets 5 × 10 × 3 in. deep were used instead of wooden top slats. They were wedged down in the usual fashion. Before the machine is started, each pocket is filled two-thirds to three-quarters full of ragging. If the bed is too loose, add more ragging and *vice versa*. The screen aperture determines the size of particles held back and this, in turn, determines the size of interstitial passages, thus controlling the work of the jig. (See Art. 2.)

Screens are rarely of the same aperture for the full length of the sieve. The underlying principle controlling choice of screen aperture is that the bed should gradually decrease in specific gravity and increase in size of interstitial passages from head to tail end. Openings are usually smallest over the first compartment in order to maintain a fairly tight bed and thus increase pulsion in comparison with suction and insure clean, fine-grained concentrate. The same opening may be maintained until near the end of the second compartment, when one to three rows of holes large enough to pass the largest particles of free mineral are introduced. These holes pass such particles while middling grains, both coarse and fine, are by this time stratified well above the large heavy grains of mineral and hence do not pass through with them. Smaller holes, although not usually so small as those over the first compart-

ment, are placed above the third compartment and fine rich middling is drawn down. Openings generally increase in size toward the end of the screen, with or without intervening rows of larger holes. At the end of the screen large holes are again provided to pass the coarsest middling particles. It is, in general, more difficult to make a clean separation of tailing from low-grade middling than to separate concentrate of suitable grade from high-grade middling, hence the latter operation is performed in as little space as possible and the remainder of the jig is given over to the former work. In a particular operation on SOUTHEASTERN-MISSOURI LEAD ORES the concentrate was substantially clean galena assaying 82.3% Pb with a specific gravity of 7.00 and the rich middling assayed 60.4% Pb with a specific gravity of 5.20; concentration criterion, water basis, 1.43. The low-grade middling assayed 4.91% Pb, the tailing sought carried 0.14%, the respective specific gravities were 2.95 and 2.82, concentration criterion, water basis, 1.07. There being only a small amount of free galena in the feed, the first two hutches, used for making concentrate, were allowed only 80 in. out of a total length of 240 in.

The last hutch is usually run with very heavy suction in order to take out all possible value in the middling.

The screens are punched plate or woven wire. At ANACONDA Ton-Cap screen was most satisfactory; it outwore ordinary woven wire cloth and was easier to keep clean.

Satisfactory operation depends on a constant feed rate and metal content. Increase in the amount of valuable mineral from any cause produces heavy beds with consequent travel of concentrate and middling toward the tail end; decrease causes loss of bed with consequent introduction of middling into the concentrate. The operator compensates for unavoidable fluctuation by shoveling off the bed when it becomes too heavy, shoveling on when the feed is light or plugging some of the screen holes or putting on finer screen. Fine gangue in concentrate may be due to leakage in the joints in the sieve tray. If the addition of ragging or increase in hutch water does not cure the condition, this possibility should be investigated. At one of the Gennamari mills, fine tailing adhering to concentrate was removed on wet screens, undersize going to tables.

Water consumption varies according to the size and character of feed, method of discharging tailing, tonnage treated, and character of product desired. With chain-drag tailing discharge it may run as low as 150 g.p.m. when treating 350 to 400 tons per day of low-grade lead ore and about 850 g.p.m. with gate discharge of tailing and strong suction in the middling compartments induced by running with open gates. In some cases, water has been conserved by removing middling, or even concentrate, as well as tailing, by scraper or other form of elevator.

Power consumption is from 4 to 6 hp. with normal load, stroke, and speed. A test at ANACONDA showed 5.2 hp. for motor, countershaft, and jig and 3.7 hp. for the jig alone.

Capacity depends on the character of work demanded but ranges from about 300 to 600 tons per day. This practically excludes the Hancock from mills working at less capacity than that at which the jig can be efficiently and continuously operated. It would be possible, however, at mills of 100 to 200 tons per day, which used one-shift crushing, to put a Hancock also on a one-shift basis, by employing suitable surge tanks.

Applicability. The Hancock jig is particularly applicable to the treatment of low-grade ores, recovering a small amount of high-grade concentrate and rejecting tailing. It does this, however, at the expense of retreatment, in circulation, of a large quantity of low-grade middling, much of which is true tailing. At many plants, also, it is necessary to retreat the tailing of primary Hancock jigs in order to recover low-grade middling that has been carried along in the crowd for high tonnage. The jig is not suited to close separation of light middling grains from gangue and hence cannot be used where mineral is finely disseminated. It has had its principal use in this country in treatment of the Mid-Continent lead ores (until 1927 in Southeast Missouri, when all jigging was replaced by tabling and flotation), but has been used to treat copper ores at Anaconda and in the Lake Superior district; also for Lake Superior iron ores. The best feed is deslimed but otherwise ungraded material ranging in size downward from about 3/8-in. Wiggin (*46 A 213*) determined that on ANACONDA ore the minimum economic size of free-mineral grain in the feed was 0.17-mm. On coarser grains the recovery was from 95 to 100%, but at this size recovery dropped to 50%. He found also, in treating deslimed <10-mm. material, that recoveries were improved by sizing the feed on a 4-mm. round-hole trommel and treating the sizes separately. Substitution of Hancock for Harz jigs in FEDERAL LEAD CO. NO. 3 MILL caused simplification of the flowsheet by reduction in number of jigs and elimination of the screens and classifiers required for close grading of feed for Harz jigs; increase in capacity in the same mill space from 2,600 to 4,000 tons per day; and marked decrease in power and water consumption per ton milled. Experience at ANACONDA was similar, higher recoveries and saving in operating and repair labor were noted. DISADVANTAGES noted at DOE RUN NO. 3 MILL (*95 J 1283*) were the low recovery of mineral finer than 1.5-mm., no way to remove coarse galena concentrate from the screen until it wore down or went into middling, and inability to maintain even depth of bed with variable feed rate. Difficulty in separating low-grade middling from tailing has already been mentioned.

Table 36. Hancock jig, Bonne Terre mill (*After Rabling*)

Material	Before changes		After changes	
	Tons per 24 hr. total	Assay, % Pb	Tons per 24 hr. total	Assay, % Pb
Feed, original	400	....	423	....
Feed, total	750	4.1	505	4.7
Concentrate	16.5	70.0	7.7	75.0
Middling	475	3.5	195	8.2
Tailing	258.5	0.9	302.3	0.7

Performance. BONNE TERRE MILL, ST. JOSEPH LEAD CO. A most exhaustive study of the work of the jig on the galena-dolomite ore of this company was reported by Rabling (*57 A 309*). The jig

was a standard 25-ft. size making concentrate from the first three hutches, middling from fourth and fifth, and tailing from the sixth. Speed, 190 to 195 s.p.m.; vertical stroke was varied by the operator between 3/8 and 3/4 in.; horizontal, 3/4 in.; depth of ragging, 3 in. The feed was the product between 9- and 2-mm. round-hole trommels. At the beginning of the testing work the results on 400 tons per day of original feed were as shown in Table 36. Sizing-sorting-assay tests of the feed and products are given in Tables 36*a* and 36*b*. Improvement in results was effected principally by change in the system of screens used, with resulting change in the character of the bedding. The final screen system is shown in Table 37 and final results in Table 36. In regular operations in this mill in 1919 the screens were as follows: sheet steel, 4-mm. aperture on compartment No. 1, 5-mm. on No. 2 with a row of 7-mm. holes at

the tailing end, 6-mm. on No. 3, 7-mm. on No. 4 with one row of 8-mm. holes at the end, 9-mm. on No. 5 with 2 rows of 10-mm. holes 3 rows back from the discharge end. Life of screen was about 6 weeks for 4-mm., 7 weeks for 5-mm., 8 weeks for 6-mm., 9 weeks for 7-mm., and 12 weeks for 9-mm. A 5-in. bed was carried. Power consumption, 5 hp. at 195 s.p.m.; 3/4-in. horizontal and 5/8-in. vertical throw. Capacity, 375 tons new ore per 24 hr. One man attended two machines. Lost time was less than 0.1%, principally due to broken rocker-arm shafts. Water consumption, 500 g.p.m. Changes in length of stroke, character of bed, and water quantity were left to the operator. Sizing test of feed as in Table 36*a*. Feed contained 12% moisture. Assays, % Pb: Feed, 2.5; tailing, 0.75; concentrate from first hutch, 75.0; second hutch, 65; third and fourth combined, 20; fifth, 2. At the RIVERMINES MILL of the same company a 5-compartment jig, 3 × 25 ft., was fitted with punched soft-steel plates, 3 × 4 ft., with 5-mm. apertures on the first and second compartments, 6-mm. on the third, 7-mm. on the fourth, and 8-mm. on the fifth. Life of screens was 30 days. Feed was all <9-mm. and 10% <10-m., and contained 40% moisture. 850 tons per day was treated, including circulating load. Water consumption, 300 g.p.m. 3-in. bed. 190 s.p.m. 5 hp. Three machines per man. Lost time, due principally to changing screens, 2%. Regulation of water and stroke were left to operator. Assays, % Pb: Feed, 3.0; tailing, 0.5; concentrate, 70; middling, 4. At FEDERAL LEAD CO. MILL No. 3, a 25-ft., 6-compartment jig with screen frame 32 in. wide was fitted with the following screens: First compartment, 3 ft. 9 in. long, 5-m. brass wire; second and third, 3 ft. 1 in. each, 4-m. brass wire; fourth, 3 ft. 6 in., 12-mm. punched-steel plate; fifth, 4 ft. 7 in., 9-mm. plate. Life of screens was 5 to 6 mo. Feed: on 12-mm., 1.4%; 10-mm., 3.1%; 8-mm., 9.2%; 6-mm., 16.2%; 4-mm., 17.9%; 2-mm., 29.3%; 2-mm., 22.9%, containing 43% moisture. Feed rate, 400 to 500 tons per day. 195 s.p.m., 3/4-in. vertical and 5/8-in. horizontal throw. 4-in. bed. Water, 190 g.p.m. 5 hp. Two machines per man. Stroke regulation left to operator. 3 to 4% lost time, due to cleaning and changing screens and general repairs. Assays, % Pb: Feed, 3; tailing, 0.65; concentrate, 70; middling, 3.5. At FEDERAL MINING & SMELTING CO., Morning mill, standard 25-ft. Hancock jigs were used on both coarse and fine feeds. (Jigging was replaced by flotation in 1926.) On the "coarse" jig the feed was all <12-mm., 66% >4-m., 26.6% >6-m. and 7.4% >16-m. with 53% moisture. Screens were 5-, 7-, 9-, 12-, and 14-mm. round-hole punched-steel plates on compartments 1 to 5 respectively. Life of screens, 75 days. 6-in. bed was carried. 180 s.p.m. length variable. 5 hp. One man attended 2 jigs and 4 sets of rolls.

Lost time, 0.05%, due principally to changing screens. Length of stroke, quantity of water, and character of bedding were regulated by operator. "Fine" feed was all <4-m.; 9.6% >6-m.; 63% >16-m., and 27.4% <16-m.; 45% moisture. Screens, punched-steel plate, 3-, 3-, 3-, 5-, and 7-mm. round holes on compartments 1 to 5 respectively; life about 75 days. 180 s.p.m. 5 hp. Attendance and lost time as above. Results for both jigs, averaged over 8 days, are stated in Table 38. ANACONDA ran extensive tests before replacing Harz-type jigs by Hancock jigs. The work was done on a 25-ft. jig with tray 20 ft. × 2 ft. 8 in. Speed, 190 to 195 s.p.m., vertical stroke 3/8 to 3/4 in.; horizontal stroke, variable. No tailing was made. Concentrate was drawn from the first three hutches, middling from the fourth hutch was circulated, middling from the fifth and sixth hutches was reground. Results are given in Table 39. Further data from ANACONDA presenting the results of competitive tests between Hancock, Harz, and Woodbury jigs are given in Table 40.

5-mm. round hole to end..	....	3 ribs

All of these mills have abandoned jigging for flotation (Sec. 2, Figs. 21, 100), but the data illustrate efficient operation, and methods applicable to other ores not so peculiarly amenable to flotation as lead and copper.

a No assays. *b* None made.

A fluorspar mill at ROSICLARE, Ill., uses four 25-ft. Hancock jigs to make a rough CaF_2 concentrate and tailing; jigs are standard construction, but rest on concrete walls instead of usual CI legs. Tailing is elevated by a built-in drag scraper 24 in. wide (*135 J 301*). Screen, 32 1/2 (wide) × 225-in., is in 4 sections, divided as shown in Table 41, starting at the feed end. The screen has two gates like Fig. 13, about 1 ft. apart and 7 ft. from tail end, for discharging coarse concentrate into the hutch. A small amount of galena is removed from the screen by hand. Power installed for 4 jigs, 20 hp. Water for 4 jigs, 300 g.p.m. Feed is <1/2-in., deslimed. Capacity, 9 tons per jig per hr. when necessary to remove galena; otherwise, as when reworking old tailings, 12 tons per hr. Table 42 gives average assays. Concentrate is subsequently crushed to pass 1/4-in. Leahy screen, then subdivided at 1/8-in. for cleaning jigs and Plat-O tables, yielding combined concentrate averaging 85.8% CaF_2, 2.3% SiO_2, and 10.6% $CaCO_3$. At EMPIRE ZINC Co., a 12.25-ft. 3-hutch jig recovers galena concentrate from the first, middling from the second (returned, usually *via* a small rod mill, to the head), and tailing from the third hutch; the tailing is further reduced to table and flotation size (*132 J 251*). Ore is largely pyrite, with galena and blende (var. marmatite) in gangue of Ca, Mg, and Fe carbonates, characteristically porous. Feed to jig is <4-m. product of a ball mill, deslimed and dewatered to 55% solids. Screen, 3 ft. 2 in. wide, has 0.194-in. openings; bedding is 00 lead shot over the first, and 5/16-in. steel balls over the second hutch; speed, 189 s.p.m. Galena concentrate is drawn periodically through

the hutch spigot. Middling and tailing are continuously removed and dewatered by vertical screw conveyors having 9-in. flights inside of 10-in. pipes, both cast in a manganese-iron alloy; short, horizontal conveyors in the bottoms of both hutches propel the solids to the boots of the elevators.

Various expedients were used to meet special problems at GENNAMARI MINES, Sardinia (*18 pt. 1 RIM, 367*). At the PIREDDU mill, roughing 400 tons of blende ore per day, at 10~2-mm., it was impossible to supply the 220 to 260 g.p.m. of water required when operating with all hutch discharges open; hence the first 5 hutches were arranged to discharge intermittently, and a small scraper elevator lifted tailing from the sixth, thus reducing consumption to 65 g.p.m. When feed size was reduced to 10~1.5-mm., tailing carried considerably more fine blende. At ARGENTIERA mill, treating <10-mm. tailing, an impinging jet was installed at the top of the tailing elevator to wash fines back into the hutch, from which they were drawn intermittently for other treatment. At the NARACAULI mill, the Hancock produced a concentrate as well as middling and tailing from <10-mm. feed; the concentrate, to which much fine tailing adhered, was screened at 2-mm., the undersize going to a table. At some of the Spanish mills of the Soc. DE PENARROYA (*loc. cit.*), water for Hancock jigs was economized by removing both middling and tailing by scraper elevators. The middling elevator was constructed at right angles to one side, as an integral part of the jig tank; partitions between the 3 hutches contributing middling were removed, and replaced by sloping chutes delivering to the elevator.

11. OTHER MOVABLE-SIEVE JIGS FOR ORES

A modified Hancock jig was developed at the HALKYN DISTRICT UNITED MINES, Ltd., Wales (*46 IMM 376, 418, 441*), to treat a coarsely disseminated lead-zinc-limestone ore. Vertical motion of the screen box is accelerated on the down-stroke by a link connection between cranks on two parallel but eccentric shafts; both vertical and horizontal motions are adjustable. The screen box, 32 in. × 14 ft., set level, spans 5 hutch compartments as follows: No. 1 (to remove fines and start stratification) 20 in. of blank feed plate at 30° slope and 32 in. of 5-mm. screen; No. 2, 32 in. of 15-mm. and 3 in. of 20-mm. screen; No. 3, 8 in. of 20-mm. and 6 in. of 25-mm. screen (Nos. 2 and 3 deliver rough concentrate); No. 4, 27 in. of 15-mm. screen; No. 5, 30 in. of 20-mm. and 10 in. of 25-mm. screen. (Nos. 4 and 5 deliver middling; the 25-mm. end trap intercepts occasional coarse galena, which passes the trap in No. 3.) Tailing discharges into the submerged boot of a chain-bucket dewatering elevator delivering to cars.

Performance. Mill feed varies, often abruptly, from 10 to 30% Pb and 2 to 8% Zn. Feed to the jig was sized between 1-in. and 6-mm. on wet screens. The jig roughed out limestone tailing, amounting to 25% of total mill feed, averaging 0.5% Pb; both concentrate (76% Pb) and middling were retreated. Hutch No. 1 was drawn every 20 min.; Nos. 2 and 3, every 40 min.; Nos. 4 and 5 discharged continuously to an elevator. Capacity, 300 tons per day; one operator attended it and 2 Harz jigs.

In a later modification, the screen box was divided by 2 weirs into 3 independent sections, each with its screen sloping toward the discharge end, the box as a whole remaining horizontal. In all sections, most of the area was covered by screen of a mesh to retain all ore (except some fine concentrate on the first), but a strip of coarser screen across the lower end of each section provided for discharge of concentrate into 3 separate hutches; a fourth hutch collected fine concentrate from the first section. The jig thus operated without bedding. Capacity, about 1 ton per sq. ft. per hr. Power for treating 20 tons per hr, 6.5 hp., or 0.33 hp. per sq. ft. of screen area.

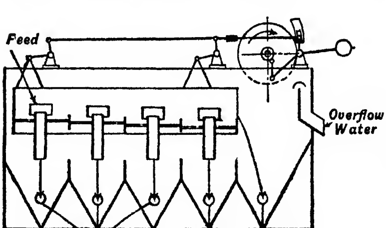

FIG. 28. Hancock-type jig, Tschiaturi.

At TSCHIATURI (*34 ME 619*) a Hancock-type jig treats manganese ores 8~0-mm. The sieve (Fig. 28) has a substantially vertical motion, imparted by mechanism situated above the jig. The screen is sectionalized, with a drop from one section to the next to produce longitudinal flow. Each section has a cup discharge for coarse concentrate.

Performance. Each of three such jigs treated 10.8 tons per hr. of <8-mm. material (see Table 43).

Table 43. Performance of Hancock-type jigs, Tschiaturi

Tailing	4.4	17.5	6.7	13.81	2.39
Overflow	....	66.0	....	....	....

a By diff. *b* Not reported.

Humboldt jig (*77 ZvDI 149*) has a movable screen frame resembling the Hancock, but the screen (Fig. 29) is in two equal segments, the front edge of the second segment being held at an adjustable distance above the rear end of the first, and overlapping it slightly. This leaves a clear space across the full width of the screen through which the coarse concentrate collecting on the first segment can fall into a narrow hutch *a* between the first and second fine hutches, while middling and tailing pass over to the second segment. In the same manner, tailing is skimmed at the end of the second segment, and coarse middling falls through an adjustable space, into a second narrow hutch *b*. Tailing discharges into a fifth and last hutch *c*. The Eisenzecher Zug treats spathic iron ore on a rougher at 50~30-mm. size (screen 8 1/4 ft. long, 2 1/2 ft. wide) and 4 finishing jigs at 30~18, 18~12, 12~6, and 6~3 mm.

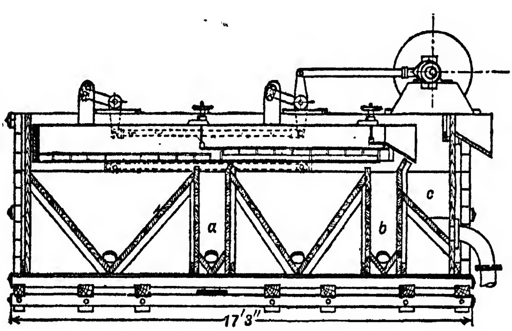

Fig. 29. Humboldt jig.

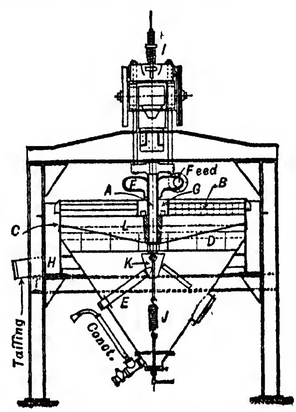

Fig. 30. Hardy-Smith circular buddle jig.

Hardy-Smith buddle jig (*105 Aa 1*) has a horizontal, circular screen (Fig. 30), with vertical motion imparted by a pitman-and-toggle mechanism, thus affording two fundamental advantages: (*a*) rate of ore travel horizontally is slowest where separations are most difficult; (*b*) sharply accelerated downstroke, quick turn, and decelerating up-stroke provide optimum conditions for unsized ore.

The screen, 6- or 8-ft. diam., rests upon 6 or 8 arms *L* radiating from a point near the lower end of the vertical shaft *A* and is held in place above and below by identical cast-iron grids *B*, with square 4- or 5-in. openings and webs 2 1/2 to 3 1/2 in. deep. Both screen and grids are segmented to fit between the radiating arms. Periphery of screen is bounded by a dam, adjustable in height, and is flexibly connected to the perimeter of the conical hutch by a rubber strip *C*. Across the top of the hutch, and just below the lowest position of the radiating arms, is a coarse grid *D* with deep flanges to prevent water waves. Water is admitted to the hutch from a tank at the same elevation as the screen, equipped with a float valve to maintain constant head. Usually only a hutch product is desired, discharged through the gooseneck; if wanted, screen product may be drawn through cylindrical cup gates discharging through hopper *K* and pipe *E*. Feed enters through chamber *F* (with a swirling motion to cause uniform distribution) and the annular overflow box *G*. Tailing flows over the dam into a launder discharging at *H*. Entire weight of moving parts is carried by the spring *I*; tension in the opposing spring *J* is adjusted until the natural frequency of the system synchronizes with that of the head motion; no vertical guides are required. Length of stroke may be varied, while running, by adjusting the position of the pitman block. Usual speed is 250 to 300 s.p.m.; power for an 8-ft. screen, 3 to 4 hp., depending on speed. Usual bedding is chilled-iron shot. Feed (best not >1/2-in.) may have any dilution. The jig is recommended in tube-mill and classifier circuits. An 8-ft. jig, thus used, is reported to have

continuously treated 32 tons of solids per day per sq. ft. of screen; a 6-ft. jig, on 40-m. deslimed sands, 15 tons. North reduction works of West Rand Consol. Mines has 18 @ 6-ft. roughing jigs, each in circuit with a tube mill discharging 750 to 1,500 tons of solids per 24 hr.; also 2 @ 8-ft. jigs for recleaning concentrate from the roughers. A 6-ft. jig, treating 850 tons per day, requires 740 tons of hutch water (cyanide sol., in this case), of which 610 tons passes off with tailing and 130 tons with 34 tons of concentrate per day containing 14.7% FeS_2 Total concentrate (614 tons) is retreated on two 8-ft. jigs, each requiring 720 tons of solution, of which 520 tons goes with tailing and 200 tons with 128 tons concentrate, averaging 30% FeS_2.

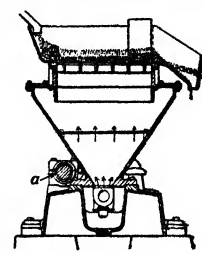

Fig. 31. James jig.

James jig (Fig. 31), for metallic ores, consists of a movable sieve box, usually less than 30 × 36 in., supported by means of a rubber diaphragm and spring-balanced connecting rods, one each side, rockers, pinned at *a* and oscillated by a suitable mechanism, causing an accelerated down stroke. A gate-and-dam discharge is located at the center of the discharge end; tailing overflows each side of the dam. Back water enters under a perforated baffle plate in the hutch.

At North River Garnet Co. (*118 J 529*) the machines are run at 225 s.p.m.; the bed is about 3 1/2 in. thick; screens are 6- to 30-m. Garnet is separated from hornblende and feldspar. Capacity is 10 to 50 tons per machine per 20 hr. depending on size of feed. About 2 hp. is consumed per sieve. At Eldorado Gold Mines, Great Bear Lake, working a pitchblende-silver ore averaging (1938) 26 oz. Ag and 1.064% U_3O_8, two sizes, 1/2-in.~4-m. and 4~14-m. were separately treated, each on two James jigs (*139 #4 J 35*). Screen on the coarse jig had 3/32-in. openings; on the fine jig, 0.063-in. Concentrate was drawn both above and below the screen; grade of hutch product was equal to or higher than the screen concentrate, provided a good bed was maintained. All tailing was recrushed and further treated (together with the primary <14-m.) by tables and flotation. Jig feed contained 31% of the U_3O_8 coming to the mill, about equally divided between the two sizes. Recovery by the coarse jigs, 71%; by the fine, 59.5%; total, 16.4% of the U_3O_8 to mill. Coarse concentrate assayed 116 oz. Ag and 28% U_3O_8; fine concentrate, 109 oz. Ag and 39% U_3O_8. Cost of jigging was 16.4¢ per ton.

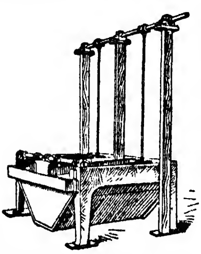

Fig. 32. Hooper vanning jig.

Hooper vanning jig (Fig. 32) consists of a shallow rectangular screen-bottomed tray open at one end, except for a shallow (1-in.) shoulder, suspended at the open end from a fixed shaft and at the closed end by an eccentric rod. The tray bottom slopes downward slightly toward the open end. A hopper-bottomed tank below the tray is filled with water to such a depth that the bed on the screen is submerged. The machine is run 240 to 330 @ 1- to 0.5-in. s.p.m., according to the fineness of the feed. Concentrate must be skimmed by hand. Hutch concentrate is discharged by spigot or by drag belt.

This jig was developed at the North River Garnet Co. for separating garnet from hornblende and feldspar and has been successful in this service. (See Sec. 3.)

12. HAND JIGGING

Hand jigging is an indispensable operation in preliminary field testing of ores, ranking with panning and vanning; it is frequently practiced in treating ores in prospecting and small-scale development work when it is endeavored to make the mine pay its way; and in certain districts, notably parts of the Mid-Continent lead-zinc field, it is established as the only method of concentration on many of the small properties.

Equipment and operation. For field testing, any small sieve such as a testing sieve, a bucket or tub of water, and small metal scraper or skimmer are all that are necessary. The screen is filled one-half to three-quarters its depth with the material to be tested, then, after careful submergence and thorough wetting, is held firmly in two hands with bottom horizontal and top just not submerged and moved up and down in such a fashion as will bring the material into partial suspension on the down stroke and allow it to settle back on the up stroke. This requires an accelerated down stroke and retarded up stroke. The usual speed is 60 to 100 s.p.m. After a small number of strokes, depending on the size of particles and relative specific gravities of the components of the bed, the impoverished surface layer may be scraped off and new feed added and the process repeated until the top of the middling layer becomes so high as to leave insufficient room for new feed. This layer is then scraped off and set to one side and concentrate is removed from the screen. Middling may then be put back to form the bed for further operations. The fine material that passes through the sieve and overflows the top is collected separately. If the jig screen is fine, this material is best cleaned up in a pan or plaque; if the screen is coarse, the fines may better first be rejigged through a bed of coarser concentrate on a fine screen, in this work accenting the start of the up stroke and working with the top of the jig-sieve box

always out of water. In this way considerable suction through the bed is induced and fine heavy mineral is thereby drawn through. Slime may be separated from this concentrate by decantation and be treated separately on a plaque.

A somewhat more elaborate testing jig may be made by suspending a jig sieve, say 12 × 12 in. and 6 to 8 in. deep by means of a rigid stirrup rod about 18 in. long, from a spiral spring of such strength that it is imperceptibly extended by the loaded jig sieve, yet extends readily under a downward pull by the operator and returns readily when the pull ceases.

When any extended operation is contemplated a more elaborate rig is needed. Figs. 33 and 34 show two forms that have been successfully used. The simpler form shown in Fig. 33 (*89 J 1265*) was used at an isolated copper mine in northern Transvaal; the form in Fig. 34 is typical of Joplin practice. This type is best used with a spring board, so arranged that the handle is about waist-high to the operator while jigging. The compartmented box is used to provide a quiet pool for slime settlement. Proportions are such that an 8-in. bed on the sieve, when submerged, just about balances the handle. Capacity of such a jig is from 1 to 3.5 tons feed per sq. ft. per 24 hr.

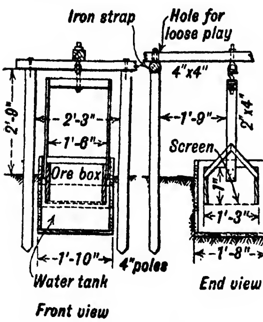

Fig. 33. Simple hand jig.

Elmore (*18 CA 1132*) says that a Joplin-type hand jig with 24×66-in. sieve in a 6-ft.×6-ft.×33-in. tank can be built at not to exceed $60 (1920).

Performance. At Santa Barbara, Chihuahua (*87 J 910*), using a jig of the first type with a 3×3-ft. sieve, 0.25-in. aperture for coarse material and 0.12-in. for finer, the results shown in Table 44 were attained in treating 3,000 tons of oxidized lead ore. One Mexican laborer made about 0.5 ton of combined screen and hutch concentrate per 9-hr. shift. Thirty jigs were arranged in two rows with a track for a tailing car down the center and room for ready access of wheelbarrows to all jigs. At Berta Mining Co., Encantada, Chih., Mex. (*10 MJA 6*), limestone-galena ore, carrying about 20% Pb and a little barite was treated by hand jigging at 2∼3/4-, 3/4∼1/4-, and <1/4-in. sizes. Jig box was 36 × 36 in., inside, and 46 in. deep; it was formed of 1-in. tongue-and-groove boards, with 2×4-in. corner posts which extended upward far enough to support the lever at a convenient height (7 or 8 ft.) above ground; the box was set about 18 in. in the ground. Basket was 35 in. square, outside, and 8 in. deep, made of 2-in. plank. It was hung by bridles and link from a hook on the lower end of a 1/4-in. rod suspended from the end of the working lever; this loose-jointed connection, together with the jar caused by teetering the lever over a square-edged (not rounded) support, was thought to be advantageous. Screen, of 20-gage steel wire, was 8-m. for the coarser, 20-m. for the fine ore; it was reinforced by ribs 1 in. deep, beveled top and bottom, and spaced 4 in. c-c. Screen concentrate was removed with a wooden scraper (to save wear on screen); to empty, remove, and repair the screen, and shovel out a full accumulation of hutch concentrate required about 1 hr. Two men in 8 hr. treated about 4 tons of ore. Concentrate was 60% Pb or better; barite, the chief impurity. Water consumed, about 20 gal. per ton jigged. In the Joplin, Mo., district (*93 J 1079*) three men operating two rougher jigs and one cleaner jig of the type shown in Fig. 34 will treat 15 to 30 tons of coarsely disseminated, non-clayey ore per 10-hr. shift. Feed is screened through 1-in. or 1.25-in. apertures; rougher-jig slots, 5/8- to 3/4-in.; cleaner-jig, 1/4- to 3/8-in.; stroke, about 1 in. on rougher and 1/2 in. on cleaner. If there is much clay in the ore it should be washed in a trough washer (Sec.

10, Art. 8) or the equivalent before jigging. Rougher jigs are run with no bed, and each charge, after stratification, is divided by skimming into tailing, middling for sale to the mills, and concentrate. Hutch product collects in the jig box for retreatment on the cleaner. On the cleaner the operator starts with a 2-in. bed and allows it to accumulate until about 6 in. thick, when it becomes too heavy to handle and is skimmed down to 2 in. again. The hutch product through the thin bed may have to be recleaned through the thick bed. Treating <3/4-in. WOLFRAMITE ORE with a quartz gangue on a jig such as shown in Fig. 34, using 10-m. screen, the procedure was to charge 70 lb. of ore, jig for 1 min. (about 150 strokes) with an average stroke length of 1 in., longer at first and shorter at the end, shovel off tailing, then charge another 70-lb. lot and repeat. About 5,000 lb. of ore carrying 5% tungstic acid was treated per day, yielding 175 lb. of screen concentrate assaying 65% tungstic acid, and 200 lb. hutch product assaying 8%. Tailing from the screen assayed 0.7%. In another district, concentrating ferberite from quartz and granite (*101 J 717*), feed, <3/4-in.; sieves, 2 to 4 sq. ft.; stroke, 0.5 to 3 in., speed about 40 s.p.m., and 2- to 3-in. bed, from 1 to 5 ton per 8-hr. shift was treated, including recleaning of concentrate to two grades, *viz.*, 50 to 63% tungstic oxide and 25 to 40%. The hutch product was only slightly enriched. Water consumption per jig was about equal to the overflow through a 1-in. pipe. Table 45 shows the performance of a hand jig on BITUMINOUS COAL.

13. DESIGN AND OPERATION OF JIGS

Factors which affect a jig bed and, therefore, determine its performance are in part conditions precedent to delivery of feed, in part structural, and in part operating, *i.e.*, variables in current control of the operator. A jig is chosen or designed to accommodate, in so far as possible, the conditions precedent; the attendant changes operating variables to complete the accommodation.

The essential requirements in jigging are to obtain and maintain a 3-layered bed comprising:

(1) A separating layer having an effective density suitable for the final separation desired.

(2) A roughing layer that will immediately reject material certainly unwanted at the jig screen, and will get doubtful material to the separating layer as quickly as possible.

(3) A presenting and transporting layer.

Separating layer. A suitable separating layer is one that absorbs or passes particles of concentrate and rejects heavy middling. It is desirable that it do these things quickly. The factors that affect the character and performance of the separating layer are the specific gravity, size, size range, and shape of the particles which form it; its depth and uniformity; and the character of the upward forces to which it is subjected.

Any characteristic of the particles in the layer that increases its resistance to dilation increases the upward pressure of the water dilating it, and, consequently, increases the constant pressure that such water (and the bed particles themselves as transmitters of the water pressure) exerts against the underside of particles seeking to enter or penetrate the bed. High specific gravity, large size, a long size range, and flat shape of bed particles all tend to increase back pressure of the bed.

Any characteristic of the bed particles that causes them to resist movement past each other increases plastic resistance of the bed. Large size, angularity, and roughness of particle surface are the principal characteristics thus acting. See Fig. 3 and the discussion thereof.

Back pressure varies as thickness of layer and as total depth of bed.

Uniformity of separating layer, both as to thickness and grain-size distribution, is essential to good operation. Any departure therefrom causes difference in back pressure at different parts of the layer, with the result that water flow increases through the region or regions of reduced resistance and boiling occurs. This reduces effective density in the regions affected and permits penetration by particles of lower specific gravity than are wanted.

The product of length of stroke and frequency is a rough measure of intensity of pulsion, *i.e.*, the impulse available for conversion into upward pressure. Within limits, inverse variation of these two elements of operation produces no material effect on the behavior of the separating layer except that boiling is less likely to occur at the higher speeds. Beyond the limits, long stroke at slow speed loosens a fine bed to an extent that reduces plasticity materially and thereby reduces effective density. At the other end of the scale, high speed with short stroke does not dilate a bed sufficiently to permit penetration by par-interstitial or superinterstitial particles.

A slow stroke, particularly one that accelerates slowly, does not develop back pressure rapidly enough to produce satisfactory dilation; a sharp stroke (rapid initial acceleration) lifts the bed as a whole (see Fig. 2 and discussion). If frequency is low this may have the effect of increasing duration of dilation, but at high frequency a tight bed with high effective density is formed, since there is little or no dilation on the lift and dilation by free-falling has insufficient time to develop.

Roughing layer has a separating function like that of the separating layer beneath it, but with a definite time factor imposed (see Fig. 4). If a particle doesn't penetrate to the bottom of the roughing layer before the rising current starts near the tailboard, it never has a chance to get into concentrate in that particular compartment. It follows that the roughing layer should have an effective density as low as is consistent with (*a*) exclusion of coarse gangue which, if it penetrated, would tend to clutter up the upper surface of the separating layer; and (*b*), with lifting out heavy middling at the tailboard. It should also have sufficient thickness to cushion against the plunge of the feed stream and to give some resistance to the start of boil-spots in the separating layer.

Top layer has the two functions: (*a*) to spread out the feed so that all particles get to the roughing layer, and (*b*) to get from the head end to the tailboard as quickly as is consistent with performance of (*a*). It should, therefore, be thin and fluid.

Conditions controlling design and operation (conditions precedent) are: (*a*) mineralogical characteristics of the feed, (*b*) its size and size range, and (*c*) its rate. Their effects are discussed below.

Design

Elements of design are: (*a*) dimensions of bed; (*b*) DROP, *i.e.*, the vertical distance from feed lip to the overflow edge of the discharge weir; (*c*) distribution of pulsator water; (*d*) accelerative character of stroke; (*e*) method of withdrawing products; (*f*) number of compartments; (*g*) screen.

Dimensions of bed all have an effect on performance. The horizontal area, taken with the feed rate, is the primary factor in determination of the time that the average particle spends in the bed, but time for a grain of a given character (heavy, light, or intermediate) is controllable over a considerable range by the operator.

The WIDTH of the screen is limited by the difficulty of obtaining an even distribution of water in the screen compartment. The practical limits lie between 24 and 36 in. With the width fixed between these limits, the required area and time are obtained by increasing LENGTH. It is better to divide the screen transversely into compartments the length of which is from 1.2 to 1.5 times the width than to attempt to get the required area in one or two compartments, even where the exigencies of mineral separation would not require the greater number of compartments. (See below.) Large area and concomitant time are particularly necessary for close separations such as between a concentrate and a high-grade middling or between a low-grade middling and a tailing, because here the bed becomes practically two-layered, with the roughing layer eliminated, and the difference between specific gravity of presented particles and effective density of separating layer is small.

Representative figures for area are given in Table 46. The limiting size of jig screen is reached when the jig members become so massive as to be unduly expensive and maintenance becomes difficult. The plunger rods on excessively large jigs break frequently and support must be used extravagantly to prevent the sides from bulging and leaking.

DEPTH of bed determines the amount of latitude left in the hands of the operator. The thicker any given layer is, the more time there is available for doing the job of that layer and the smaller the part of its function that is loaded onto the underlying layer. (For methods of separate control of depth of various layers see *Operation*.) When a clean finished product is desired, a deep bed is necessary. A large difference between specific gravities of the mineral species to be separated makes a relatively shallow bed permissible. A large proportion of heavy mineral, which makes for a large amount of locked middling and, consequently, a thick roughing layer, permits use of a shallower bed than otherwise. Depth of bed is properly reckoned in terms of number of grains, hence for a given kind of service the actual depth will be greater for coarse feeds than for fine, but the depth reckoned in number of grains will be greater on a jig treating fine feed. In any jig making a gate draw the layer of concentrate must be at least three grains deep, if the cup is set at the minimum height, in order to insure exclusion of mid-

dling grains from the pen. This necessary minimum depth will be relatively greater the smaller the particles. The overlying middling layer constitutes the testing zone in which concentrate is separated, and must be deep enough to prevent penetration by lighter grains during local disturbances. The required depth will vary from that of the concentrate layer to twice that figure. The surface layer need not be more than one grain deep, but limitation to this depth will require such a high surface velocity in order to move the desired tonnages that it will be difficult to attain complete settlement and saving of the difficult grains. The minimum depth for coarse feeds is, say, 7 times the diameter of the larger particles constituting the gate discharge; better 12, if clean concentrate is to be taken; the depth may be less with the coarsest feeds, if middling only is to be

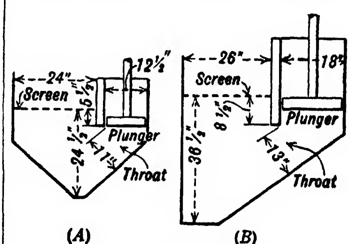

FIG. 35. See Table 47.

roughed out. With fine feeds (2 mm.) the minimum depth is about 20 times the grain diameter. With much top or cross water the bed must be relatively shallower in order to get rapid removal of values in a soft bed to counterbalance the rapid horizontal flow.

Number of compartments depends upon the duty demanded, upon size of material treated, and upon operating considerations. A single bed treating a natural ore can make one finished product only. Hence, if the jig is required to make one finished product only, a single-compartment jig will do the work. If two concentrates of different minerals are to be taken but finished tailing is not desired, a three-compartment jig is necessary, making clean heavy mineral on the first compartment, clean mineral of intermediate specific gravity on the third, a middling product consisting principally of locked grains of the heavy and intermediate-weight mineral in the second, and a product over the tailboard of the third compartment containing little or no free mineral but much middling. If clean tailing is likewise desired, from three to nine compartments will be necessary, depending upon whether one or two concentrates are to be taken and also upon the relative specific gravities of the gangue and valuable minerals, as well as upon the grade of tailing desired. For a one-mineral separation such as quartz-galena,

three compartments will serve, if tailing requirements are not rigid, otherwise four; corresponding figures for blende-quartz are four and five. For two-mineral separation, such as galena and blende from quartz, five compartments will be required to yield relatively high-assay tailing to nine for low-assay tailing with ores in which the mineral is intimately disseminated in the gangue. The number of compartments necessary increases with decreasing size of feed. At CLAUSTHAL (*100 J 426*), jigging closely sized feeds and making lead and zinc concentrates and a tailing, a 4-compartment jig was used on the 11∼2.8-mm. size and a 5-compartment jig for the 2.8∼1.4-mm. material and also for the classified sands <1.4-mm. At BLEISCHARLEY (*112 A 952*), treating short-range lead-zinc-dolomite ore, feeds down to 14-mm. are jigged on three compartments; nine smaller sizes, each on five compartments.

Compartmentation aids operation; it increases the number of concentrate draws, thus making it easier to maintain uniform thickness of the bottom layer; it gives greater flexibility and so permits closer regulation of grade of final products; and permits greater over-all drop, which makes for easier control of the top layer. The principal drawback is that it increases total bed perimeter, which tends to increase leak of overlying layers into concentrate.

Drop, taken with cross water, controls the flow rate of the top layer. Since there are definite limits to water control and it is the principal minute-to-minute control of the operator, drop should be made as steep as is consistent with good operation, in order that normal top-layer flow may be taken care of without much cross water. A large drop takes care of rushes of feed without clogging the flow, and permits loosening the rush by additional cross water without danger of churning up the top of the roughing bed. On the other hand, a large drop with a lightly loaded bed means considerable churning at entry and a relatively thin top layer. The churning helps to loosen the bed, but there are better ways of doing it. A thin top layer tends to raise grade of tailing. In former practice the drop averaged about 1 in. and this figure is probably the best today for slow, close work on closely sized feeds. For rapid work, on roughly sized or unsized feeds, from 2- to 3-in. drop is common.

In the DeMier "level" jig (*IC 6342*), employed in the Tri-State zinc field for retreatment of the low-grade, deslimed sand middlings, the screens of the six 32×42-in. compartments are set at the same level, forming a practically continuous screen from end to end of the jig, which is otherwise of typical Harz design. A mechanical rake, similar to that on Dorr deslimers, with blades about 18 in. apart, moves the top layer of ore toward the discharge end.

Distribution of pulsating water is aided by keeping the path of the water through the under-sieve box as straight as possible; making the conduit within which the water pulsates as uniform as possible in cross-section; and supplying vanes directly under the screen to break up large-scale eddying. The first desideratum is served by placing the pulsator directly beneath the screen, but this introduces other complications, *e.g.*, hutch discharge and mechanical drive. Much the same end is served by making the hutch deep and extending the partition between plunger and screen compartments correspondingly far down. This has the disadvantage of considerable loss of headroom on hutch concentrate. Richards recommended that the lower edge of the partition should extend at least 0.4 times the width of the screen compartment below the screen in coarse jigs and 0.33 times in fine. Table 47 shows what can be done by attention to such details. The nearest approach to a uniform water passage in the usual top-drive longitudinally partitioned jig box with V-bottom is obtained by carrying the partition down to such a depth that the distances from the bottom of the partition to the sloping walls are equal and equal to the widths of the compartments. Some makers fabricate the bottom semicylindrical to do away with the variation in cross-section due to the point of the vee and the junctures of bottom with side walls, but since hutchwork tends to settle and build up to a chord of the cylinder, no permanent advantage results.

Usual practice is to extend the screen-supporting grid several inches below the screen in order to prevent large-scale eddying. Some makers use longitudinal supporting bars extending progressively deeper at increasing distances from the central wall. Plunger and screen areas are usually made equal in order to eliminate velocity changes with resulting eddies; if areas are unequal the plunger area should be the smaller.

Screen affects the action of the bed and determines the relative sizes of grains in gate and hutch discharges. The screen must be rigid, if boiling of the bed is to be prevented and a uniform thickness of bottom layer is to be maintained. This requires that the screen be supported on a grate and tacked or wired thereto and that the grate bars be spaced with regard to the flexibility of the screen. The screen should have the maximum possible percentage of opening in order to obtain the highest fluidity of bed with minimum water and also to obtain uniformity of water distribution and prevent boiling. Screen openings should converge upward to reduce blinding. Punched plate has maximum rigidity and the most favorable shape of opening, it is easily cleaned by a scratching tool and is but little damaged thereby; but woven wire has the greater percentage of opening in the fine sizes. Slotted punching, $1/16 \times 5/8$-in. to $3/16 \times 3/4$-in., hit-and-miss endways, is preferred in Joplin, and is common on Malayan tin dredges. It is placed with the long dimension across the jig. It does not blind so readily as the round hole, is more readily cleaned, and is stiffer for a given percentage of opening. Grates have been used to a considerable extent to replace screens in Mid-Continent mills. Grates are usually made in sections, 6 in. wide by the length of the compartment, and with $1/16$- to $3/16$-in. spacing. Osage orange wood is used for wooden grate bars because of its hardness and the fact that it does not swell and close the openings between bars. Wooden grates clog less than iron, because they are more smooth and flexible; they also resist acid water. Life of wooden grates is claimed to be 8 to 12 mo. under hard service in acid water against 2 weeks for the iron grates. Such grates have less percentage of opening than cloth or punched plate, but they are more rigid, blind less readily, and are more easily cleaned. SCHUBERT GRATE, designed primarily for coal jigs (*67 G 834*), aims to increase capacity by accelerating the forward movement of the bottom layer, without resorting to excessive speed, length of stroke, or water supply. Iron bars, having the cross-section shown in Fig. 36 placed crosswise to the direction of travel, impart a horizontal component to the motion of the rising current. Among other effects, this promotes an even horizontal distribution of the several layers in the jig bed, and thus assists in maintaining uni-

form water velocities. Open space in the grate is about 51%, compared with 33% in a punched screen with 7-mm. holes. Experiments (*32 ME 312*) showed that resistance offered by the screen is the largest item in the power consumption of a jig in normal operation, its importance increasing rapidly with velocity of the water.

Size of aperture depends on the size of feed, the place that concentrate is to be taken, and the grade of concentrate desired. Coarse feed requires and permits large apertures. Concentration through the screen requires larger apertures than concentration on the screen permits. If apertures are small, small particles will be kept on the screen, thus reducing the size of interstitial spaces in the concentrate bed. The result is to increase interstitial velocities, but also to increase the differential between upward and downward velocities in favor of upward; this keeps fine gangue out of hutch concentrate and facilitates drawing down fine mineral. Hence a relatively smaller aperture is used when clean concentrate is desired than when the principal endeavor is for clean tailing. With short-range feeds the screen aperture is made slightly less than that of the sizing screen preceding except that the jig-screen aperture is rarely less than 2 or more than 5 mm. With natural or long-range feeds, the aperture is determined to a considerable extent by the character of work desired and the minerals in the feed. In Wisconsin a typical set of screens on an 8-cell rougher jig, treating 3/8-in. lead-zinc feed and making practically all concentrate from the hutch, is 1/8, 3/16, 1/4, 1/4, 1/4, 3/16, 3/16, and 3/16-in. The screens on the following 7-cell cleaner had 3/32, 1/8, 3/16, 3/16, 3/16, 1/8, and 3/16-in. apertures. In the Tri-State field, a typical 7-cell cleaning jig, producing clean galena from the first and clean blende from the third and following cells, mainly through the screens, has apertures, 3/16, 3/16, 1/4, 1/4, 3/16, 1/8, and 1/8-in. When a jig is run to take all of the concentrate through the screen the aperture may be made considerably larger than the largest particle of concentrate in the feed, and a ragging of proper specific gravity, composed of particles larger than the apertures, is placed on the screen before jigging starts. In such practice at Clausthal, with a feed between 2.8- and 2-mm., the screen apertures were 3- to 4-mm.; with feed 2- to 1.4-mm., the apertures were 2- to 3-mm.; four grades of sand finer than 1.4-mm. were jigged on and through 1-mm. aperture. In the N. J. Zinc mills, treating five short-range feeds between 2.41- and 0.58-mm., apertures on each jig are about twice the size of the largest grain in its feed, and the ragging is about twice the diameter of the apertures; this completely prevents blinding of the screens. On Malayan tin dredges recovering cassiterite practically all <10-m. and most of it much finer, roughing-jig screens commonly have 1/8-in. slots and ragging is 3/8~1/2-in. hematite grains; cleaning jigs have 1/16-in. slots and 1/4-in. ragging.

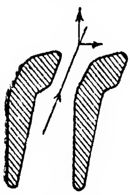

Fig. 36. Schubert grate.

Grids for supporting screens are made of wood or cast iron. Wooden slats are placed from 1 to 6 in. apart according to the amount of support required, and should run at right angles to the length of the jig so as to cause least disturbance in the plunger-water currents. Slats should be beveled to an edge at the top to lessen the area of dead space above them; also on the bottom, to reduce eddying resistance. Where there is much acid in the water wooden grates are practically indispensable. Cast-iron grids usually have square or rectangular openings, 3 to 6 in. on a side. Grids and screens should be readily removable. This can be done by making the screen-compartment liners in four pieces and holding them in place with wedges, as shown in Fig. 26, and making the hood (gate) also readily removable. By rings or hooks attached to the grate, and a small grappling sling suspended above the jig, a screen may be quickly removed with most of the bed in place; this can be dumped on the replacing screen, allowing the first to be cleaned or changed at leisure. Screens are frequently sloped 1 to 2 in. in their length toward the discharge end in order, by greater depth, to compensate for impoverishment and maintain uniform resistance to the water currents. When a screen is to carry permanent ragging, it is usual to add a grid above the screen, similar to the one below, forming pockets 1 to 3 in. deep to restrain lateral movement. At Broken Hill, N. S. W., the upper grid is cast in soft brass so that it can be drawn down tightly against the cast-iron lower grid without cracking.

Concentrate draws. The best known is the gate-and-dam shown in Fig. 37. Discharge is prevented until there is a sufficient bed of heavy mineral formed to seal the opening between the lower edge of the gate and the screen. When the dam is lowered discharge begins and continues until a condition of equilibrium is reached, when the hydrostatic head of the column of heavy mineral H within the pen, when in partial suspension in the upward current and therefore free to flow, is just less than that of the composite column of heavy mineral, middling M and light mineral L without, friction losses due to flow of the bed of heavy material across the screen and under the gate constituting a deduction from the head of the bed outside the pen. With any given setting of the dam, increase in the amount of heavy mineral in the bed will cause corresponding increase in flow over the dam; decrease will cause cessation. This type of draw is usually placed at the front side of the screen compartment near the discharge end. Thus placed it requires that most of the concentrate travel at an angle more or less acute to the forward travel of the overlying bed as a whole, part of it at right angles and a certain part must actually travel against the stream, if it is to discharge. The result is necessarily some loss of free mineral over the tailboard of the compartment, but the most serious objection to this placing occurs when concentrate must be removed rapidly; the surface of the concentrate layer then slopes steeply down to the bottom edge of the pen, causing a boiling at this point and consequent contamination of the concentrate by material from the overlying layers. This type of draw is sometimes placed at the discharge end of the compartment with the concentrate-discharge spout running in the compartment partitions. This placing is superior as to removal from the bed, but will give some trouble by clogging. Fig. 13 shows a pipe draw designed on the same principle; it makes the concentrate travel in a more favorable path than the side draw. The portion of the jig bed adjacent to any draw is coarsest. This produces a

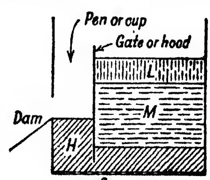

Fig. 37. Gate-and-dam jig discharge.

"live spot" in the bed that will permit gangue to pass down into the hutch, and wear on the screen is greatest at this point, which aggravates the trouble. The size of the pen in discharges of the gate-and-dam type and of all ore passages should be sufficient to allow free movement of impounded material, *i.e.*, at least three times the diameter of the largest particles, better more. There are a number of other draws whose fitness may be tested according to the method of analysis given. HUTCH-WORK JIGS, of both fixed- and movable-sieve types, intended to deliver concentrates mainly or exclusively through the screen, sometimes need facilities for discharging accumulations of coarse concentrate into the hutch; this occurs most frequently when jigging materials yielding large proportions of concentrate. Such discharge gates have an advantage over those above described in that they may be placed anywhere on the screen, as found best to maintain an even distribution of bedding. For continuous discharge, the CUP GATE operates on the same principles as the gate-and-dam; a short piece of pipe comes vertically through the screen and projects a short and adjustable distance above it; its upper end is surrounded and covered by an inverted cup, the lip of which is supported at a fixed or adjustable distance above the screen, making an exit for concentrates approaching from all sides. If desired, such a gate may be arranged to deliver its concentrate separately through the side of the hutch, with its flow under control by an outside valve. For intermittent discharge, the PIN DRAW, as found in the TRI-STATE field, is a short piece of 3/4-in. iron rod stuck into a hole through the screen, and withdrawn at intervals. A device used on fluorspar jigs at ROSICLARE (*135 J 301*) comprises a 5×5-in. piece of 1/4-in. steel plate with a 1 1/2-in. hole at its center, bolted to the screen over a corresponding hole. An 8-in. piece of 1 1/2-in. pipe is welded to the upper side of the plate, leaving a cutaway space 3/4 in. high halfway around the bottom of the pipe. A loose piece of 2-in. pipe, 12 in. long, with its lower end similarly cut, fits over the smaller pipe and regulates discharge as turned.

Hutch draw must be capable of close adjustment in order that suction may be carefully controlled. Such adjustment results in frequent clogging, hence the draw should be of such variety that it can be opened wide to remove obstruction. When the ordinary pipe-and-plug spigot is used, the working plugs can be fitted into the center or bottom of a 6-in. plug, which is readily removed when necessary. The ordinary molasses gate, 1 1/2- to 3-in. sizes, is frequently used. Rotating slush gates (Fig. 38) are common when continuous hutch discharge is to be maintained.

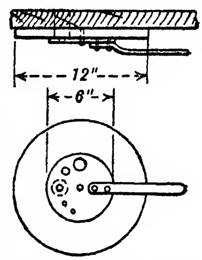

FIG. 38. Slush gate for jig hutch.

Plunger having the same area as the screen permits symmetrical construction, minimum changes in velocity of water currents between the two compartments, and readily understood adjustment. There is some advantage in making the plunger larger than the screen, which allows shorter plunger stroke and larger throat, thus producing a free action in the beds and reducing power consumption. Plungers smaller than screens are found mainly in those jigs of Harz type which employ accelerated pulsion strokes. For most efficient mechanical operation the plunger should fit its compartment as snugly as possible without binding. The usual fit is between 1/16- and 3/16-in. clearance all around. Small plunger clearance creates strong suction and where this is undesirable a close fit must be compensated by plunger valves; otherwise excess back water must be used to cut down suction. Fig. 39 shows a form and arrangement used on a Malayan tin dredge, made of 1/4-in. rubber backed by 1/4-in. board. A loose plunger requires a longer stroke than one that is tight-fitting. Clearance must be greater when water is fed above the plunger than when introduced below. Introduction of water below the sieve is likely to cause collection of air under the plunger with consequent uneven action. Plungers are built up of five courses of 1-in. tongue-and-groove stock, thoroughly wet with good white-lead or asphalt paint, laid with alternating courses at right angles and closely nailed. The outer courses are cut shorter than the center to allow for rocking of the eccentric. Courses both sides of the center course are shortened about 1/8 in. all around to provide water packing. Eccentrics should be of extra-heavy pattern with spherical sliding surfaces to prevent binding. They should be evenly spaced around the shaft to equalize motor load and avoid rhythmic vibration. It is a convenience if they are graduated to show length of stroke. The bottom of the plunger should never rise above the sieve.

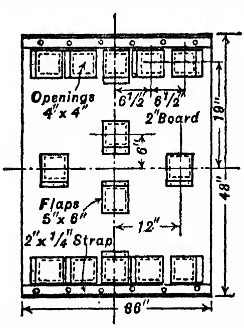

FIG. 39. Arrangement of flap valves on a large jig plunger (bottom view).

Jig box and frame. All dimensions are substantially fixed by the rules already set down. The hutch product cannot be drawn clean unless the bottom is hoppered both ways to the draw valve. The usual practice is to carry the front wall straight down. If of wood, the walls should be not less than 3-in. surfaced plank, except for very small jigs. Even with this weight there will be some bulging (BREATHING) with long strokes if the compartments are long and the span of the planks correspondingly great. All planks should be carefully tongued and grooved or grooved and joined with close-fitting feathers, and the joints should be set in white lead. Transverse partitions should be dapped into the walls and the centerboard dapped into the transverse partitions. Fig. 7 shows a cheaper method of wall construction, using 2×3- or 2×4-in. scantlings set in paint and packed with wicking, then securely spiked. This is particularly suitable for bull jigs (Art. 6), which would require very heavy planking. Posts should be at least 6×6-in., better 6×8-in. in large jigs, with caps and sills the same width and 1 or 2 in. deeper. Mortise the posts into cap and sill, but provide for draining the sill joint. Transverse tierods should be bored through the body of a transverse plank rather than let in in place of a feather, otherwise a difficult leak will occur. Strap bolts (Fig. 6) are easier to put in and just as satisfactory as through rods from cap to sill. Floor space may be saved by placing jigs back-to-back, or face-to-

face. Jig walls are sometimes built of reinforced concrete about 4 1/2 in. thick. (*109 J 1115.*) Factory-built jigs are usually of sheet steel with welded joints. N. J. ZINC jig is assembled from specially designed cast-iron plates.

Transmission machinery. Shaft should be 2 7/16-in. minimum for fine jigs with compartments up to 36-in. length; 3 7/16 will carry a long-stroke plunger in a 48-in. compartment. Pulleys should be keyed and set-screwed, and of ample face. Tight-and-loose pulleys should always be provided. Common flat boxes will serve, but adjustable ball-and-socket bearings will pay for themselves many times over in ease of maintaining alignment.

Character of pulsator stroke has a marked effect on the performance of the bed. (See under ***Separating layer,*** p. 46.) The factors are average speed, stroke length, and acceleration. Acceleration is, almost of necessity, built into and fixed with plunger and diaphragm-type jigs, but is an operating variable in the air-pulsated types. Stroke length is an operating variable in all jigs; from the designer's standpoint the problem should be to make variation as easy and quick to achieve as possible. Speed is not an operating variable in most cases, but should be made so, if possible. Despite that intensity of impulse is, for a given mechanism, satisfactorily controllable through stroke length alone within limits, a much greater flexibility could be put into the operator's hands by providing this additional control. (See also ***Length of Stroke,*** p. 53.)

Operation

Control in operation is effected by changing the effective density of the separating bed. For superinterstitial and par-interstitial grains this may be done by varying either the liquid pressure or the plasticity; for subinterstitial grains plasticity is not a factor in resistance, but change in plasticity is accompanied by changes in interstitial current velocities that are important.

Minute-to-minute control of most jig operation is effected by change in water quantities, in thickness of separating layer, and in feed rate. Air-pulsated jigs permit change also in length and sharpness of stroke without stopping and independently. Stroke length can be changed on mechanical jigs by stopping, but sharpness of impulse is not a variable except as velocity of the pulsator is changed by varying length of stroke at constant speed. Screen aperture is a simple structural change. Size, size distribution, and density of separating layer are effective controls in jigging through the screen but not otherwise.

Water for control is fed to a jig either above the screen (TOP WATER) or beneath the screen (BACK WATER); the sum of all of the water flowing across a given compartment is the CROSS WATER. All other things being equal, quantity of cross water controls horizontal flow of the upper layers of the bed. Back water affects the difference between rising and falling water velocities; much the same effect is obtained by control of water withdrawn from the hutch during operation. When downward velocity exceeds upward the effect is called SUCTION.

Effects of back water are shown in Tables 48, 49, and 50. In Table 48 it is apparent that suction increases time-factor for a given recovery with short-range feeds, but is essential when the heavier mineral is subinterstitial. Table 49 shows the same general picture, but additionally that for short-range

feeds with relatively low concentration criteria it is necessary to have a loose bed (low effective density) to maintain capacity, although good recovery can be made in time with a tight bed. Comparing Tables 48 and 49 brings out that penetration of the tailing (top) layer of a tight bed by superinterstitial particles of galena is about 10 times faster than for sphalerite, but that the difference is materially less for subinterstitial particles. Table 50 shows the effect of change in suction on the distribution of con-

centrate between screen and hutch, and that this difference is greatest for par-interstitial sizes. Note that Table 50 shows differences in penetration of the bottom or separating layer while Tables 48 and 49 demonstrate penetrability of the top layer. Fig. 40 shows that with a long-range natural feed the par-interstitial grains have great difficulty in penetrating the bed, that the largest of the subinterstitial sizes get through reasonably well, but that when pulsion is sufficient to separate coarse concentrate, the finer subinterstitial grains largely go over the tailboard. (For further discussion of the effects of back water see *Length of stroke*.) Excessive cross water must be avoided, if tailing loss is to be kept down and the jig beds are to be kept in good condition. Where large amounts of back water are required to keep down suction, there will be excessive cross water on the later compartments unless special means are taken to rectify the condition. Water may be drawn off above the level of the bed. A long jig may be broken near the center and the feed dewatered between the two parts, but this involves lost head room and increased floor space.

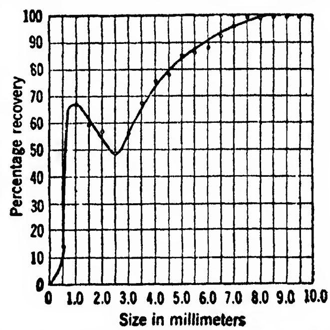

FIG. 40. Efficiency curve of a single-jig mill (*95 J 785*).

Thickness of separating layer is controlled on a jig with natural bed by varying the rate of concentrate draw from the screen; with ragging, by adding or taking out. The thicker the layer the higher its effective density, all other things being equal. Also the thicker the layer, the looser, in general, are the upper layers, unless speed is too high to permit the bottom layer to dilate properly. Hence an operator thickens a bed to raise grade of concentrate, or, with proper stroke conditions, to loosen the top and make penetration to the separating layer easier while at the same time increasing cross flow. (See also *Depth of bed*.)

Feed rate must be decreased when other controls fail to lower tailing assay to the desired extent. The result is, of course, to give more time for heavy mineral to get through the roughing layer.

Length of stroke is directly dependent upon the number of strokes per minute, unless the latter are so few that there is an appreciable rest period between pulsations. In any case the length of stroke must be sufficient to produce a certain amount of dilation.

If the jig is running at relatively high speed, the length need not be so great as when low speed is used because of the greater velocity and hence greater lifting effect of the high-velocity current. For a similar reason length of stroke at a given speed need not be so great for light ores as for heavy ores. When the endeavor is to make clean concentrate, the bed should be maintained as compact as is compatible with the desired recovery by using a short and rapid stroke, and pulsion should be accented by

using a large amount of back water; on the other hand, when clean tailing is the desideratum, the bed should be kept loose by long, slow strokes and strong suction obtained by the use of little back water. A relatively short, rapid stroke with much back water is used for rich, heavy feed, while for low-grade feed, a long, slow stroke and little water are usual. Hence, a rougher jig requires a longer stroke, lower speed, and less back water than the corresponding cleaner. For separation of low-grade middling from tailing the usual practice is a long, slow stroke, shallow bed, and a small amount of back water. This adjustment also has the result of overcoming the bad effect of the large volume of cross water on the later compartments. In the WISCONSIN ZINC FIELD the operators test for the necessity of change in stroke by increasing the specific gravity of bed; if this raises the grade of concentrate, stroke length should be decreased.

With a given maximum size of particle, unsized feed requires a shorter stroke than sized feed because of the greater lifting effect of the water when the interstices of the bed are filled with fine material. Similarly a fine screen retains more fine material in the bed and shorter stroke can be used. High speed accompanies short stroke in order to maintain capacity. If a long stroke is used with unsized material, the bed is loosened so much that it boils and fine gangue is drawn down on the return stroke. If the bed becomes impoverished, there is a tendency to mat and choke the sieves, hence with low-grade feed, it is best to maintain a bed of coarse concentrate. Coarse feed requires a longer stroke than fine feed. Flat and thin pieces (floaters) require a short, rapid stroke, a thin, loose bed, and as little cross water as possible. Speed must be kept uniform or it will be impossible to hold a bed on the sieve.

In air-pulsated jigs the bed may be tightened by increasing the rate of pressure rise without changing speed or stroke length.

Screen (see p. 49).

Ragging. The constitution of the separating bed is not an operating variable with a feed of given characteristics when screen concentrate is being made. The most that can be done is to change the size range by change of screen aperture and amount of suction, thus controlling the amount and size of material drawn into the hutch.

When using ragging, size, size range, shape, and specific gravity are operating variables. Normally the ragging is of substantially the same specific gravity or slightly lighter than the concentrate. If the specific gravity is greater than that of the concentrate, excessive pulsion is required to produce movement. This results in boiling of the upper layers and increased tailing loss. A similar result follows if the ragging is too coarse or of too great uniformity of size. Ragging of low specific gravity tends to bank up against the tailboard; hence, unless special precautions are taken, such as inclining the screen against such flow or placing baffles across it at intervals, it is necessary to use a thin bed.

When jigging through the screen the interstices in the bed determine the size of grains that can pass and, in conjunction with other operating features, the strength of suction. Ragging about three or four times the diameter of the maximum grain it is desired to draw down is usually provided. Maximum suction is attained with maximum interstices; hence coarser and more uniform bedding is used on the later sieves, where clean tailing is sought and the grade of hutch product is of minor importance. If the valuable mineral of the ore abrades readily, ragging of more durable material of the same specific gravity is frequently used; thus iron balls or punchings or lead shot will form a satisfactory bed for making galena concentrate, pyrite or magnetite for chalcopyrite or blende, and feldspar for slate in coal jigging; steel shot is the usual bedding on jigs for washing alluvial gravel. On the later compartments of a jig ragging is usually middling of proper specific gravity, but artificial bedding is sometimes provided. At CALUMET & HECLA middling grains were used to bed finishing jigs treating the hutch products of primary jigs that bedded themselves. If the bedding grains are much heavier than the concentrate, as, for instance, when iron slugs are used as bedding for pyrite or blende, the bedding is not lifted on the pulsion stroke and merely serves to decrease the sieve openings.

An ore that makes a small percentage of concentrate requires a thick bed; a high-grade ore gives satisfactory results with a thin bed and heavy suction.

Feeding. The principal requirements are that the rate be regular and that the material be spread evenly over the entire width of the screen. Screen-concentrate draws respond slowly to increase in concentrate supply; hence a sudden increase in feed rate or metal content usually causes valuable mineral to pass over the tailboard; decrease will cause the discharge of low-grade material from the cup unless the draw is correspondingly altered. When making hutch concentrate only, sudden or large increase in feed rate causes increased tailing loss; decrease may cause some lowering of the grade of concentrate, but this will not be serious. Uneven distribution of feed puts the task of distribution on the jig, with consequent loss of capacity.

Capacity is determined by the solid-carrying ability of the cross current and the rapidity with which heavy mineral is dropped by the cross stream and absorbed or passed by the bottom layer. High capacity and high fluidity are concomitant. For discussion of limits see the preceding paragraphs on design and operation. Capacity of a given jig under given operating conditions is proportional to sieve area, with width the predominant dimension and length contributing rather to recovery. Usual figures for capacity estimates for ores, when two or three clean products are sought, are 0.5 to 2.0 tons per sq. ft. per 24 hr. for fixed-sieve types and 4 to 9.5 tons for movable sieves. Jigs operating to scalp out heavy concentrate in grinding circuits, and to rough out the small amounts of heavy mineral from alluvials, operate at much higher capacities (see Sec. 2).

Power depends upon sieve area, percentage of open space in the screen, speed, length of stroke, depth and weight of bed, and upon design of the jig box, as affecting the course of the water current between plunger and screen. *Wiard* gives the formula, Hp. = $AD^{1/2}/5{,}000$, where A is the sieve area in sq. in. and D is the diameter of feed in mm. For estimates, 0.1 to 0.15 hp. per sq. ft. of total sieve area is safe. Preceding articles give power consumed or installed for various types of jigs. Except in anthracite washeries it is an unimportant part of concentrate expense.

Experiments on a Harz-type jig (*32 ME 312*) in which the work required to overcome all mechanical and hydraulic resistances to flow of water through an empty screen of 1-mm. sheet punched with 2-mm. round holes with 1.5-mm. bridge, and having 32.7% opening, when jigging 15 kg. of ore sized 3~4.5-mm., indicated that at low speeds, insufficient to dilate a bed, work increases rapidly with increase of speed, and the proportion of total energy expended on moving ore exceeds that for other purposes. At higher speeds, sufficient to dilate the bed, screen resistance increases with speed, more rapidly than ore resistance, and screen resistance predominates, while bed resistance remains fairly constant, or may even diminish. Replacing the punched sheet by a woven-wire screen with 56.5% opening, and substituting 6~10 mm. ore, the total energy consumed by the jig was reduced 25%.

Water consumption varies with the size of feed, specific gravity of the minerals, depth of bed, size of screen aperture, frequency and length of stroke, and according to whether pulsion or suction is accented.

Three-compartment, 24×36-in. jigs treating 3-m. lead-zinc ore at Daly Judge used about 11,000 gal. per 24 hr. treating 75 to 90 tons. Two-compartment, 24×36-in. jigs at Doe Run No. 3 mill treating classified feed used 30 g.p.m. each, treating 30 tons per 24 hr. At Gennamari a 4-compartment, 36×42-in. jig treating 15~4-mm. lead ore required 100 g.p.m. for 45 tons per shift. Jigging <3/8-in. blende, a 5-compartment, 30×42-in. jig required 150 to 200 g.p.m. Further data on water consumption of individual types of jig appear in preceding articles.

Cost of jigging ranges from 5¢ to 15¢ per ton jigged, according to the tonnage treated. The principal items of expense are labor, power, and water. The cost of operating jigs in grinding circuits is much less than the above minimum, since the jig imposes no appreciable additional burden on the grinding-mill operator, and power and water consumptions are low.

SHAKEN BEDS

Long-range semistationary beds formed by shaking are utilized on shaking tables and in gold pans. The characteristic quality of such a bed is what may be called REVERSE CLASSIFICATION, *i.e.*, an arrangement of the grains of the same specific gravity roughly into strata decreasing in size of grain from top to bottom of bed. Grains of mixed gravity arrange independently in this characteristic size distribution, but with the heavier particles of each particular size in equilibrium at a lower level than that of their lighter counterparts. There are, consequently, in such a bed, strata comprised of large grains of heavy mineral and smaller grains of light mineral.

The essential condition for formation of a shaken bed is movement of the support with sufficient vigor to dilate the mass, but sufficiently gentle to maintain all grains in substantial contact. The agitation may be substantially parallel to the plane of the bed, as on a shaking table or a shaking screen, or at right angles or a steep angle to the plane of the bed, as on a vibrating screen. But if the degree of agitation is such that the particles maintain substantial contact at all times, then any particular part of the bed offers transcendent viscous resistance to superinterstitial particles, while the resistance to parinterstitial and subinterstitial particles is relatively low. Hence the latter penetrate more or less readily. If the mechanical impulses act, as in the pan or shaking table, to cause movement of particles along lines lying more or less in planes parallel to the bed upper surface, and in so doing cause these to lose some of their contacts in such planes, the bed dilates more, and particles of superinterstitial size with respect to the particular level can penetrate downward. However, if such particles penetrate too far, they will be mechanically floated out of the fine zone, since on each substantially horizontal disturbance in that zone causing them to move, the resistance to any downward component of movement will average higher than that to upward movement, while as the mass settles to rest again, the finer particles will penetrate any openings below more readily than the coarser.

The fact that fine light mineral stratifies on a level with coarser heavy mineral in such a bed is conclusive evidence that composite density is not the prevailing element in effective density. It follows that plastic resistance *is* the prevailing property.

Penetration of this type of bed demonstrates that its effective density increases with decrease in bed-particle size and with increase in size of penetrating particle; for any given stratum it is substantially equal to the submerged density of its component particles against grains of its own size, but is lower for grains of smaller size.

It follows from the equilibrium arrangement of the long-range semistationary bed that it is distinctly less fluid, all other things being equal, than the short-range semistationary type. Otherwise fine-grain strata would be penetrated by coarser grains of solids of their own and higher gravities.

14. PAN; ROCKER

The pan and rocker are primitive apparatus used commercially only for hand or manual concentration of gravels containing minerals of high unit value, such as gold, diamonds, and tin. The pan is also used widely as a testing tool for concentrating any finely divided valuable material of relatively high specific gravity associated with waste of equal and larger sizes.

The gold pan (Fig. 41) is made of stiff sheet iron with the rim turned around a heavy iron wire for stiffness. Enameled-iron pans have the advantage of not rusting, but chip easily. Aluminum pans bend and dent too easily. Amalgamated-copper pans are sometimes used for cleaning up black-sand concentrate. The usual size is 15 to 18 in. diameter at the top, 2 to 2 1/2 in. deep, with the side inclined 30° to 80° to the bottom. *Wilson* recommends a 10-in. pan for prospecting. The weight is 1.5 to 2 lb. The inner surface should be smooth, and be kept free from grease and rust. Rust pitting helps save fine gold, but makes clean-ups more difficult. A pan will save particles varying considerably in size, but for best work the heavy particles should average smaller than the lighter waste.

FIG. 41. Gold pan.

Manipulation. See Sec. 19, Art. 22, for detailed procedure.

When panning gold gravel as a commercial operation, if there is much heavy sand present, it is best not to attempt complete separation with each pan, but to collect and later work up together the concentrate from many pans. In such work black sand (magnetic) may be removed (best dry) with a magnet and the gold, if amalgamable, may be collected with mercury, although this is not commonly done. Otherwise careful panning or blowing is necessary to make the final separation. In prospecting work when it is necessary to collect the gold from each pan separately, the quickest method of collection is to draw the colors into a head and then pick them out separately with a sharp-pointed metal or wooden tool. When there is a quantity of gold in the heavy sand, sizing in a series from 20- to 100-m. before attempting final separation is helpful (*20 IMM 197*).

Amalgamation in a pan is commonly practiced when panning down sluice concentrate. About 1 oz. mercury and 5 lb. concentrate are agitated in the pan under water until all visible gold is taken up, when the sands are panned away, taking care to hold back mercury and amalgam and to encourage it to run together. If much black sand is present, reduce the weight of concentrate panned.

Blowing is done by placing dried gold-bearing concentrate, preferably freed of magnetic material, on a sheet of paper or smooth metal about 2 ft. square, spreading to a layer one grain deep near one side of the supporting surface and then blowing across the grains toward the opposite edge with just enough force to move the lighter grains, which will then travel across the separating surface, leaving gold behind. Loss of some fine colors is to be expected.

Mechanism of concentration in a pan is, in a way, an epitome of gravity concentration, and as such worthy of careful examination.

(*a*) Assuming a gold-gravel feed, the first operation is a rough concentration by SIZING, in which eye and hands substitute for a screen, and the products are coarse concentrate and a finer middling (see the screening operation in gold dredging, Sec. 2, Art. 21).

(*b*) The second step, SUSPENSION, involves formation of a relatively loose bed by a form of rotary agitation in which, progressively, different layers of the bed from the top down, initially left roughly in place relative to the earth during the swirling movement by their inertia, are subjected to an action similar to that which a washboard in horizontal position, supporting a layer of baseballs, exerts on the layer when it is moved horizontally. It is not the action of the water that causes the suspension; this is attested by the fact that the fine gravel can be suspended dry by a pan similarly swirled when resting on a table top.

(*c*) STRATIFICATION. Heavy grains settle through the bed because their weight overcomes the effective density of the bed (Art. 2). There is a certain amount of reverse classification in the bed also, although this is not so pronounced with water present as with dry panning.

(*d*) Washing down the surface layer of settled solids to the toe brings scour into play with resulting FILM SIZING (Art. 32) over a somewhat roughened surface. The coarser particles roll over such a surface the more readily, just as a bicycle rolls more readily across a rutted road than does a more lightly loaded roller skate. Hence the first tailing is relatively coarse, while subsequent tailings, obtained by repetition, are progressively finer.

(*e*) The final pan step comprises floating a rich tailing out of a heavy bed, the latter being formed as was the lighter early bed in (*b*).

(*f*) The float product of (*e*) is streamed over the relatively rough settled surface of the remaining rough concentrate and the sink is streamed on the smooth surface of the pan.

Flowsheet of the pan is shown in Fig. 42.

Capacity. The charge for a pan 16 to 18 in. diameter is from 15 to 30 lb. of ordinary gold gravel. Such material averages about 135 lb. per cu. ft; hence 243 @ 15-lb. pan loads = 1 cyd. A skillful worker can pan 100 charges in 10 hr.; gravel containing many boulders works more rapidly, and fine or cemented gravel at about 75% of the rate stated.

A pan in the hands of a skilled operator will make a lower grade of tailing on any ore amenable to gravity concentration than can be made in the most elaborate gravity mill. Concentrate will not, however, be of as high grade as can be made in a mill.

Batea; Battel (Fig. 43) is an equivalent of the pan, used in Central and South America and in certain Asiatic countries. It is usually made of wood, less frequently of sheet iron. It is claimed that the wooden surface is superior to iron for catching and holding fine gold. *Bowie* states that Honduras mahogany is the best wood. The usual size for prospecting work is from 15 to 20 in. diameter with an angle of 150° to 155° at the apex of the cone, making the depth at the center from 1 5/8 to 2 1/2 in. Bateas 30 to 36 in. diameter are used in diamond washing in Brazil and in washing tin gravels in the Dutch East Indies. Load runs about 170 per cyd. (*56 MM 218*).

8. Blowing.

Mechanical pan is built for large-scale prospecting on a limited area and for clean-up of large-scale placer operations. It comprises an assembly of four superimposed nested cylindrical units (24-in. diam.) held together by clamp bolts and mounted on a horizontal gyrating base driven by a 3/4-hp. motor (gasoline, Diesel, or electric). The top unit is a 2-deck screen; the lower are, in order downward, shallow pans discharging, one to the next, at such points as to cause feed to flow across the full surface, aided by a slight tilt of the pan bottom. The lower screen is usually 10-m.; the upper is a scalper. The top pan is bare copper if amalgamation is desirable, otherwise sheet steel like the lower; the lower pans are floored with matting (rubber, heavy canvas, or thin coco) held down by coarse wire screen. The clamp bolts, with wing nuts, are hinged to lugs on the gyrating base and swing up to engage open lugs on the screen box. Height to top of feed hopper is about 30 in. Water consumption is said to be 1 to 2 parts by weight per part of gravel; capacity, 1 1/2 cyd. of easy gravel per hr. Shipping weight is 500 lb.

Dry panning. See Art. 38.

Rocker (Fig. 44) is used in the same kind of service as the pan, but has somewhat greater capacity. Rockers are of many designs and sizes but all consist essentially of a screen box (*a*) for rejecting coarse pebbles, an inclined apron (*b*) serving the double purpose of transporting undersize to the head of the rocker trough and of catching gold, and an inclined riffled trough (*c*) with flaring sides; all mounted on two rockers (*d*). The screen box may be provided with a handle (*e*) which serves both as an aid in lifting out and a grip for the operator in rocking, or the rocking stick may be longer and attached to the side of the trough near the head end. The SCREEN BOX ranges from about 12 × 12 in. in small prospecting rockers to 20 × 24 in. in large working rockers, and is 6 to 8 in. deep. It is sometimes made with a low side at the head end and the bottom inclined slightly toward the low side, in order to effect continuous discharge of oversize. The screen is occasionally a grizzly, but better perforated steel plate, 10 to 18 gage, according to the service. The screen aperture depends to some extent on the character of the gravel; it varies between 1/4 and 3/4 in., normally is about 1/2 in. Percentage of opening should be as great as possible. The APRON is normally made of canvas tacked onto the frame in such a way as to leave a slight belly. Rubber sheeting backed with canvas (*93 J 1266; Peele 10–538*) and galvanized iron have been used. The slope of the apron is from 1.5 in. per ft. upward. The TROUGH proper is usually between 12 and 18 in. wide at the bottom and 3 to 6 ft. long, with slightly flaring sides from 1 to 2 ft. high at the deepest part. The bottom piece should be clear, soft lumber that will not shred or "rough-up" when wet, under the action of the gravel. The slope of the trough ranges from 0.5 to 1.5 in. per ft.; it can be varied as desired by blocking the assembly, but the slope of the apron changes reversely. RIFFLE CLEATS of wood 1/2×1/2-in. to 1×1-in. are placed on the bottom of the trough and held down by strips nailed to the sides. The arrangement varies. Usually all are transverse but occasionally the upper half of the trough is riffled longitudinally. Canvas, corduroy, burlap, or blanket is sometimes used to cover the bottom. *Janin* recommends burlap as

both most effective and most easily available. The fabric may be covered with riffles made of expanded-metal lath. The TAILPIECE at the lower end of the trough is usually between $^3/_4$ and 1 $^3/_4$ in. high at the center and from 1 to 3 in. higher at edges. It serves to hold a bed in the trough. The ROCKERS should have no more curve than is necessary to effect distinct agitation of the material in the machine; more makes the labor of rocking unduly fatiguing without any corresponding gain in concentrating efficiency. Dressed 1-in. lumber is heavy enough. The joints should be tight. Warping may be prevented by light tierods and the use of light-weight metal corner straps. See also *Janin, p. 36.*

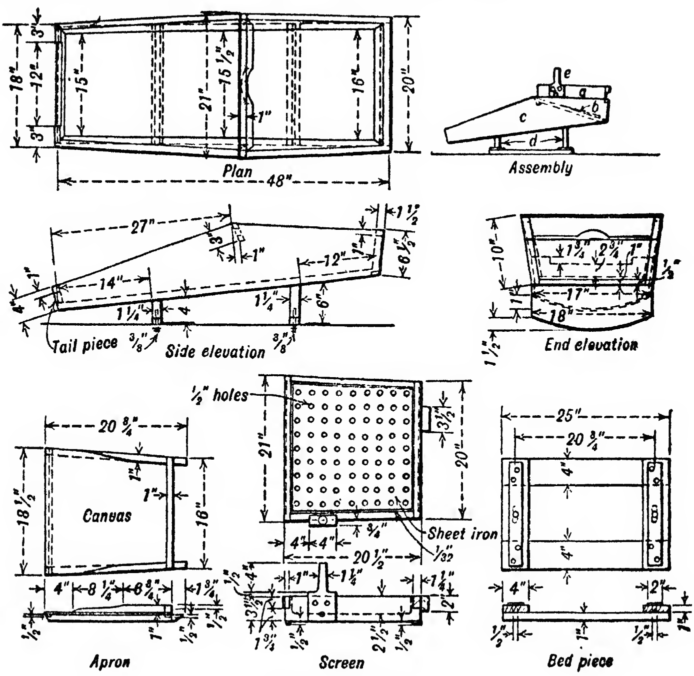

FIG. 44. Rocker.

Manipulation. Material is shoveled into the screen hopper and washed by means of water, preferably clean, poured in from a dipper. At the same time it is forked over and disintegrated and coarse clean boulders are thrown out. More water is then added slowly and the machine is rocked in such a way as to cause material to progress along the floor of the trough, to loosen the bed at each stroke, and to maintain even transverse distribution of the solids. *Wilson* states that one swing should be sharper than the other, to effect stratification, or even that a bumping block may be used, but either procedure will cause heaping of solids and concentrate at one side of the trough with consequent difficulty in manipulation and loss of values. When the deposit of gold has worked down to near the tailpiece, or sooner if the exigencies of the operation demand, a clean-up is made. The material behind the tailpiece is shoveled out, the screen is then carefully washed and removed, the apron lifted out, and the contents washed carefully into a pan for re-concentration. The riffles are taken out and carefully washed and the deposit in the trough is then washed on the plane bottom by streaming as described in Art. 32. Final clean-up is usually made in a pan.

The longitudinal progress of tailing depends upon slope, shake, and wash water. Slope should be adjusted so that satisfactory longitudinal progress is effected with minimum consumption of water and energy and so that sand does not pack behind the tailboard and in the riffles. Slope must be steeper for a gravel containing much fine sand than for one of more pebbly character; likewise if much heavy sand (black sand) is present a steeper slope is necessary than otherwise. If gold is fine, the bed must be loose; hence a relatively steep slope is required.

Capacity varies with size. Purington (*Bul. 263, USGS*) gives 3 to 5 cyd. per 10-hr. day for 2 men working steadily, one feeding and removing boulders and tailing, the other rocking and washing. *Van Wagenen* gives 3 cyd. per 10 hr. per man in ordinary gravel and 2 cyd. in cemented gravel. Capacity is less in prospecting work on account of more frequent clean-ups.

Water consumption varies widely, but from 50 to 100 g.p. cyd. treated is sufficient if the gravel is not too fine, slope sufficient, and water is used sparingly. Water may be reclaimed in pools, if conditions are right; connecting pools aid clarification.

Applicability. A rocker catches coarse gold readily but will lose much fine gold. The loss will be greater with clayey or cemented gravel or if muddy water is used. In some cases quicksilver placed in the riffles will aid in catching fine gold, but since the loss occurs rather through failure to effect settlement of the gold than by washing it out of the riffles, this expedient is rarely successful. The rocker is rarely used except in sampling when a device of greater capacity than the pan is needed, and in cleaning up concentrate from sluices and gold tables.

North Carolina rocker consists of a semicylindrical trough, closed at both ends, with two longitudinal riffle cleats near the bottom. The charge with water is first rocked gently to effect stratification, then the apparatus is rocked differentially in such a way as to throw waste over the rim and leave the gold and heavy sands between the riffle cleats. Clean-up is made in a pan.

Mechanical rocker (*116 J 334*) driven by crank from a water wheel has been used to treat ordinary gravel at the rate of 5 cyd. per 8 hr. The trough was 14 in. × 12 ft.; the screen hopper sloped in the opposite direction from the trough and discharged oversize of a 0.5-in. screen automatically over a riffle. A power rocker (*IC 6786*) 49 in. long, 27 in. wide at top and 21 in. at bottom, with 5/8-in. screen, 3 aprons sloping 3 in. per ft. and covered with canvas under 1/2×1/4-in. riffles, rocked 40 @ 6-in. s.p.m. by a small gasoline engine, treated from 1 to 3 cyd. per hr. according to the clay content of the gravel, with 2 men working.

More finished forms of mechanical rockers have been manufactured by several of the mining machinery houses. A typical form comprises a small wash trommel, a transversely shaken riffled trough, and a small flight conveyor, mounted on a light frame on a plank base and driven by a 1-hp. gasoline engine. The trommel is 12 to 16 in. diam. by 30 to 36 in. long, with a feed hopper for shoveling in about 4 1/2 ft. above the ground; it is provided with angle lifters for light scrubbing; trommel oversize by spout, and fine gravel and coarser sand by conveyor, discharge at the other end at a height of about 36 in. Small rectangular tanks standing on the plank floor provide for some clarification of water. A small centrifugal pump, taking suction on the clear-water tank, delivers to a spray on the inside of the trommel and to the back of the feed hopper. The riffles are molded onto a flexible rubber trough which fits removably into the rocker frame; the latter is shaken 200 times per min. Rated capacity on easy gravel is 2 1/2 cyd. per hr. Dimensions, set up, are 54 in. (high) × 70 (wide) × 84; uncrated weight, 600 lb.

SHAKING TABLES

Introduction. Modern shaking tables are concentrating devices that consist of substantially plane surfaces, inclined slightly from the horizontal, shaken with a differential movement in the direction of the long axis, and washed at right angles to the direction of motion by a stream of water. The earliest form of shaking table was shaken in the direction of the slope, causing the heavy material to climb against the flow of pulp. Salzburg, Schemnitz, Halley, and Gilpin County tables for heavy ores were of this class. All are now obsolete. The simplest and earliest form of typical side-slope table is the Rittinger bumping table (*Ed. 1*). The separating action of a side-slope table is shown diagrammatically in Fig. 45; *A* is the feed side, *B* the concentrate end, *E* the tailing side, and *D* the head-motion end. The deck tilts as indicated by the arrow, is reciprocated at right angles to this slope by means of pulley *P*, eccentric *X*, and the flexible connecting rod *R*, and is stopped suddenly at the end of the forward stroke by the bumping block *G*. Feed is introduced at *F*, slime flows directly down slope and leaves at *S*, granular material is moved toward *C* by the bumping action and is washed by water introduced at *W*. Tailing discharges at *T*, middling at *M*, and concentrate at *C*. In modern types of shaking tables longitudinal cleats are fastened to the upper surface of the table deck, or riffles are cut into the surface, the resulting riffles in either case being arranged variously. Some makers build the deck in two or more planes slightly inclined to each other. Decks of different makes differ in outline from the rectangular form, and head motions and methods of deck suspension have been greatly improved over the original Rittinger model. With a smooth-surfaced table such as the Rittinger the maximum size of feed that can be treated efficiently is 1 mm. For years the maximum size of feed treated on riffled tables was 2.5 mm. and in most mills it was less than this. With some of the present methods of riffling, however, base-metal ores are treated as coarse as 1/4- to 3/8-in., and coal as coarse as 2 1/4-in. has been handled successfully.

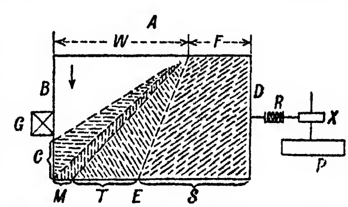

Fig. 45. Sketch of action of a side-slope bumping table.

15. PRINCIPLES OF SHAKING-TABLE ACTION

Separating action. As feed comes onto the table, its transverse down-slope flow is stopped by the riffling and it is held in a series of parallel longitudinal troughs. Shaking does the same thing to the bed thus formed as swirling does to the feed in a pan (Art. 14),

and reverse classification and stratification according to specific gravity occur simultaneously, with the result that the pulp is soon arranged roughly as in Fig. 46, item *b*. Each specific-gravity species is arranged in a vertical column graduated as to size; all columns terminate with the finest sand sizes on a common base (the deck), and extend upward a greater or smaller distance toward the top of the supporting riffle cleat, the column of lightest material being the longest.

The beds as a whole, concurrently with their formation, move in the riffle troughs from the mechanism end (*D*, Fig. 45) toward the concentrate end *B*, under the impulse of the uneven shaking motion. The more direct and consequently greater frictional drag on the lower layers causes them to move the faster; the difference in longitudinal movement of the different layers in a given cycle is what causes dilation (see Art. 14).

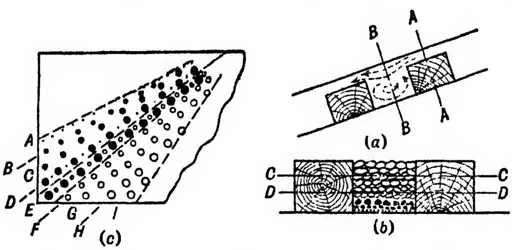

FIG. 46. Action of material on a riffled shaking table.

The height of the riffles decreases from *D* toward *B*. Hence as each transverse section of bed moves along, its upper layers successively lose the support of the cleats, and the transverse stream of water shears them off and rolls them down slope toward side *E* (Fig. 45).

The forward ends of the riffle cleats terminate (usually) on a diagonal line corresponding in position substantially to the line between clear and shaded areas in Fig. 45. Upon reaching this line the material remaining in the riffle troughs, consisting now of only the lower strata of the original beds, is subjected on the smooth inclined plane of the deck to film sizing by the cross water (Art. 32). As a result the larger particles of a given specific gravity wash down the more rapidly, as do the lighter particles of a given size range.

Thus at any given moment the horizontal distribution of the surface grains on the table deck near the line of termination of the riffles is as shown in Fig. 46, item *c*, with the smallest heavy grains, which resist transverse washing most effectively, forming line *A;* the largest heavy grains, which are readily rolled by the water, mixed with the fine light sands, along the band *D–F;* and the larger light grains, which were first robbed of their support, reaching the tailing side in the band *F–I*.

During the time that the beds are in the riffle troughs, the impregnating water is subject, along the line of the riffle tops, to the drag of the water stream flowing transversely over the top (Fig. 46, item *a*). The effect is to set up eddies as indicated in the figure. These wash out subinterstitial grains (SLIMES), which flow along thereafter in suspension in the stream and discharge in the band *S*, Fig. 45.

Thus the shaking table is essentially a continuous mechanical pan in which the shake has the primary function of dilation of the bed, and the secondary function of moving the successively diminished remnants of the original bed to those portions of the table deck on which the actions of the pan, therein occurring in a time sequence, take place simultaneously. It should be noted also that here, as in other shaken-bed apparatus, the stratification in the bed is, in itself, the first step in concentration, and that action in shaking beds differs therein from that in pulsating beds, where feed is presented to preformed separating layers which are statistically permanent.

The idealized arrangement of Fig. 46, item *c*, is modified considerably by the character of the riffling; irregularities in deck surface, motion, and water supply; differences in shape of grains of the same mineral and size; and by the presence of middling grains.

Feed. It follows from the discussion of table action that in order to treat particles on a shaking table they must settle out of the cross stream of feed water at a sufficiently rapid rate to form beds in the riffles at the feed corner; they must have a sufficient size range to permit distinct reverse classification, but not so great a range that the water currents necessary to scour out tailing on the cleaning plane (unriffled portion) will carry concentrate too far down slope. This allowable range is greater the larger the concentration criterion.

Richards (*38 A 556*) found in treating natural feeds of artificial quartz-galena mixtures on a Wilfley table that with <2-mm. feed there was marked retention of quartz between 0.7-mm. and 0.15-mm. sizes in the concentrate, while but little quartz of coarser and finer sizes was retained. With this same feed galena appeared in the tailing in amounts exceeding 1% at 0.2-mm. and the amount rose to 17.5% in the <0.08-mm. size. The slime from this run all passed 0.45-mm. and assayed 18.9% galena; there was no galena in the slime >0.36-mm., but 10% appeared in the >0.28-mm. size. Middling amounted to 21.5% of the total feed. The coarsest sizes assayed 75% galena and there was gradual diminution to a minimum of 3.68% at >0.20-mm., with a marked increase to 32.23% at >0.08-mm., and further

increase to 90.5% in the <0.08-mm. size. In treating <1-mm., < 0.5-mm. and <0.25-mm. feeds the results were similar except that the grade of total concentrate increased with increasing fineness, corresponding to decreased retention of intermediate-sized quartz; grade of tailing correspondingly increased, with accompanying decrease in grade of middling and slime. In every test maximum retention of quartz occurred at a size range beginning at between one-quarter and one-third that of the largest grain in the feed. The data are summarized in Fig. 47.

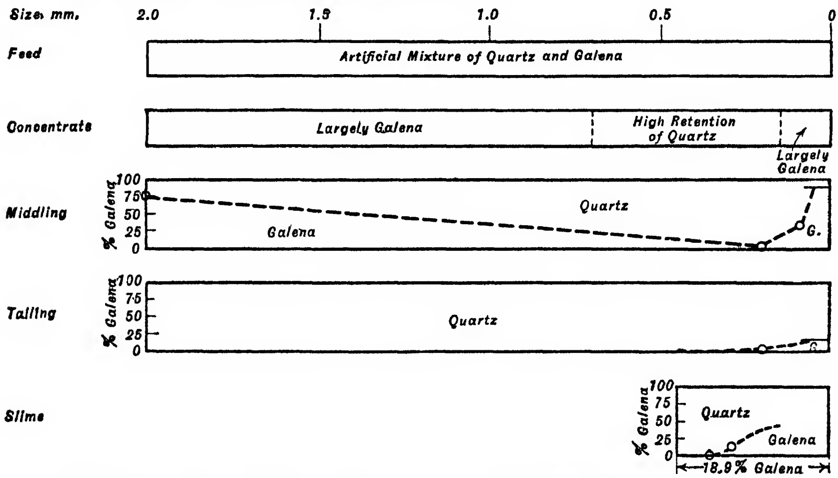

FIG. 47. Size-composition analysis of the products of a Wilfley table (*after Richards*).

The general distribution of minerals and sizes shown in Fig. 47 could have been predicted from Fig. 46, item c, but Fig. 47 points out significant sizes and size ratios that must be borne in mind in using shaking tables.

(1) Slime losses are unavoidably high. The table may be used as a slime separator but not as a saver for slime-size mineral, even when this is as heavy as galena; much of this mineral which drops into the riffles from the slime band is washed out with the tailing, and a large amount is carried into the middling as riffle support disappears.

(2) Fine gangue cannot be scoured from a roughened concentrate surface with an amount of cross water that will fail to roll coarse concentrate. Thus the figure shows that even with enough cross water (and slope) to put much coarse galena into the middling there was still high retention of fine quartz in concentrate.

(3) The tests on finer feeds show the same general distributions, so that they can be portrayed simply by moving the limiting size-scale point to that occupied in Fig. 47 by 2.0, and extending the intermediate scale proportionately. But with finer feeds less cross wash is necessary; the surface of concentrate is smoother, hence less fine gangue is retained and less fine heavy mineral is washed into middling; more heavy mineral deposits in the riffles from the slime and the assay of slime falls; but some of this deposited heavy mineral washes into tailing, the assay of which may, therefore, rise.

(4) Feed should be slime-free except as the table is purposely used as a deslimer. It should not be so coarse that excessive cross water is necessary to wash gangue off from the resulting coarse heavy-mineral layer on the cleaning plane. The size range should be short enough to eliminate the band of high gangue retention in concentrate.

(5) Since fine heavy mineral can be held up in concentrate under conditions that wash down coarse gangue, a classified feed is desirable. The same cross-wash conditions put much coarse galena in middling, hence a very short-range feed is undesirable.

Desliming of feed is an aid to recovery in the operation of all concentrators operating with fine-sand beds. The reason would appear to be that the suspended slime has the effect of increasing the density of the interparticle medium, causing it to suspend and carry fine values for a longer time than the machine time-factor. This effect was demonstrated quite definitely at BUNKER HILL AND SULLIVAN (*IC 6314*) where desliming of feed to Frue vanners (Art. 24) increased capacity tenfold, raised grade of concentrate from 55 to 69% Pb, and lowered tailing from 3.3 to 0.7% Pb. Desliming involved discard of 14% of the weight of the feed, carrying 15% of the total lead, and assaying 7.44% Pb, but over-all recovery was thereby increased from 55% on total feed to 76.9%. Similar effects have been noted in operation of shaking tables and gold tables.

TYPES OF SHAKING TABLES

Tables are called sand or slime tables according to the size of material that they treat, and are classified as roughing or finishing tables according to the character of the service. Sand tables usually have relatively deep riffles, over a majority of the surface at least, and

the space between cleats is usually not more than $^3/_4$ in. to 1 $^1/_4$ in.; slime tables are not riffled so deeply, and the space between cleats is usually much wider than on sand tables in order to form pools of relatively quiescent pulp to induce settlement of solids. Slime tables always have a portion of the deck unriffled. But any sand table that has an unriffled portion may be used for slime, and slime tables may be used for sands, if the settling pools are not too large. Roughing tables are usually riffled full length (Fig. 52, item *c*) and the riffles are comparatively deep. These tables are thus enabled to treat large tonnages and yet save fine mineral with the coarse in the form of a low-grade concentrate, at the same time rejecting an impoverished tailing. Finishing tables, with a few exceptions, have an unriffled portion for cleaning out fine gangue from the concentrate streak; the riffles are shallower than on roughing tables, and, in general, less resistance is offered to cross travel of solids than on a rougher. While in some mills the same table with different operating adjustments is used for both roughing and cleaning, this is not, in general, good practice, and it is doubtful whether superior efficiency can be demonstrated for it in any case. Such practice has the advantage of lessening the stock of repair parts that must be carried, with consequent economy, but such saving will rarely compensate for the losses or reduced capacity incident to misuse of tables.

16. WILFLEY TABLE

Description. The Wilfley table (Fig. 48) is a side-slope shaking table riffled over somewhat more than half the surface, the riffles on the original type (Fig. 52, item *a*) terminating along a diagonal line extending from the forward end of the feed box to the corner between tailing side and concentrate end.

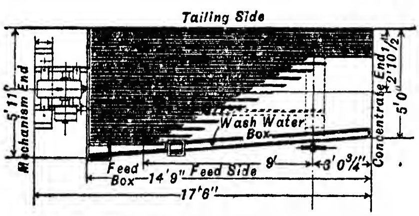

FIG. 48. Wilfley table (No. 6; right-hand).

Construction. Fig. 48 gives dimensions of the standard Nos. 6, 11-D, and 14 tables, all alike except for foundations, as noted below. Top of the feed box stands 3 ft. 3 in. above floor when the table is level, 6 in. higher when tilted to maximum slope. The deck is built of redwood strips laid flat at 45° to the axes of three longitudinal beams of pressed steel, wood-filled, and four additional longitudinal members. The whole is carried on two transverse steel trusses, each with two slipper bearings which rest in supporting bearings on the frame.

FOUNDATION is of steel, wood, or concrete. The steel base of No. 6 table consists of two 12-in. channels 15 ft. long, spaced about 24 in. apart by cast-iron separators. They carry two circular machined seats in which rest cast-iron bolster yokes with suitably machined surfaces. The yokes carry cross members built up of 3-in. channels. In No. 14 table, a 12 × 16-in. timber replaces the longitudinal channels, and pressed steel is used for the cross members. Table No. 11-D is mounted on two concrete piers (with a third pier for the head motion), which saves about 30% in shipping weight as compared with No. 6. The seats for the slipper bearings of the deck are bolted to the transverse deck-frame members. As shown in Fig. 49, the upper ends of the rockers are curved to the radius of their oscillation, whence the motion of the deck is rectilinear. TRANSVERSE TILTING is effected by power screws engaging bronze tilting nuts in the bolster yokes and actuated by suitable gearing from a hand wheel located at the feed side near the concentrate end. A permanent longitudinal tilt upward toward the concentrate end, ranging from $^3/_8$ in. to 1 $^1/_4$ in. in the length of the table, is provided for; the normal tilt is between $^3/_8$ and $^5/_8$ in. When the longitudinal tilt is too steep, concentrate may refuse to climb and may pack in the riffles. *Richards* cites an experience with two-mineral separation in which the lead content of zinc concentrate changed from 2 to 8% with change in longitudinal tilt from $^5/_8$ in. to $^3/_8$ in.

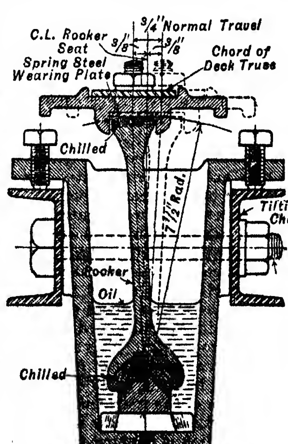

FIG. 49. Deck-support rocker for Wilfley table.

HEAD MOTION is of the pitman-and-toggle type illustrated in outline in Fig. 50. The essential parts are the pitman *a*, pulley-driven eccentric *b*, toggles *c*, and yoke *d*. The forward toggle abuts against a fixed block *e*, and lost motion is prevented by compression in spring *f* between the yoke and the fixed block *g*. The yoke is attached to the table deck by rod *k*. In the modern, enclosed, self-oiling head motions, the yoke *d* is composed of two cast-steel ends, connected by two steel rods, the latter passing through bronze bushings in the wall of the housing. Horizontal movement of the outer end of the

right-hand toggle for a given vertical displacement of the inner end is greatest when the divergence of the toggles from a straight line is a maximum, which is at the end of the forward stroke; it is least when the divergence is minimum, and this is at the end of the backward stroke. Hence with uniform rotation of the drive pulley the deck velocity increases from the beginning of the forward stroke to a maximum at the end of the stroke while the return stroke starts at maximum velocity and decelerates until the end. The backward stroke is effected entirely by the toggles, acting against the spring pressure and the inertia of the moving parts; the forward stroke is effected by the spring, but the spring tension is set to prevent lost motion so that the velocity of the forward stroke is controlled by the toggles. Graphical analysis of the motion is shown in Fig. 51, positions 1 to 8 inclusive being those occupied at eight equally spaced moments of time in one revolution of the drive pulley. In the graph (Fig. 51, *c*) the slope of the tangent to the curve at any point is a measure of the velocity at that point and the curve clearly shows acceleration from 1 to 5, representing the forward stroke of the table, and deceleration from 5 to 1. To ADJUST THE SPRING properly, loosen until a slight knock is heard then tighten just enough to remove the knock. Further tightening increases wear and power consumption and may cause spring breakage. LENGTH OF STROKE and, to some extent, the SHARPNESS thereof, are controlled by vertical adjustment of the fixed toggle block *e* which is lowered to lengthen and sharpen the stroke and raised to shorten it. The usual range of STROKE and SPEED is 1/2 in. @ 300 r.p.m. for fine, and 3/4 in. @ 260 to 280 r.p.m. for 20- to 65-m. feed. Maximum length of stroke on the standard table, 1 in.; maximum range of speed, with independent 1.5-hp. motor, 220 to 350 r.p.m., adjusted by vari-pitch V-belt sheave manipulated by hand wheel.

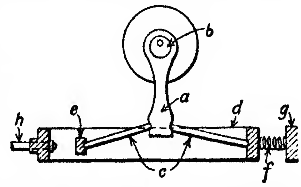

FIG. 50. Diagram of Wilfley-table head motion.

COVER is rubber when delivered by the manufacturer, and this is now the preferred covering, having many times the life of the formerly standard linoleum. The rubber should contain enough zinc oxide filler (*e.g.* 39%) to prevent absorption of water; rubber with 2 to 3% ZnO was found unsatisfactory (*IC 6658*). Pyroxylin-covered fabric (Mine-Fab), cement, and glass have been used. One of the S.E. Missouri lead mills found cement surface unsatisfactory because unavoidable seepage of water warped the wood floor of the deck.

Riffles are usually formed on linoleum and similar surfaces by tacking on wooden cleats, but the riffle may be grooved into lineoleum or cast into glass or rubber. Softwood (sugar pine) attached

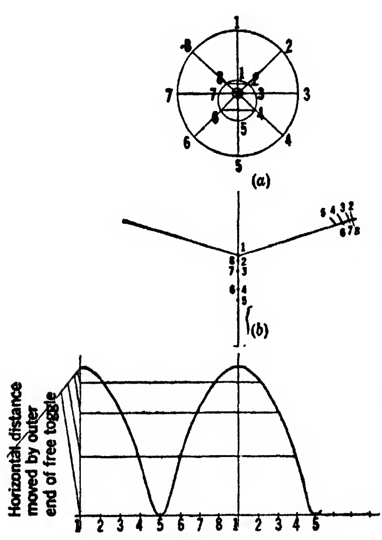

FIG. 51. Analysis of motion of Wilfley table.

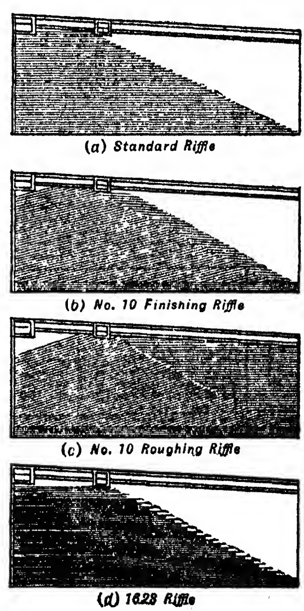

FIG. 52. Rifflings for Wilfley tables.

riffles are usually used in finishing service, maple or oak in roughing service or with coarse abrasive feed. Riffles have been made by bending 16-gage galvanized iron into unequal-leg angle sections, using the short side as the riffle cleat and the long for the bottom of the riffle (*112 J 180*). These increased the capacity of a No. 9 Wilfley 25%, the cost of laying was 20% less than for wooden cleats, and on the basis of the usual local average life of 5,000 tons for soft-pine riffles the respective costs per ton of feed were \$0.015 for wood and \$0.008 for iron. STANDARD RIFFLING on a Wilfley table (Fig. 52,

item *a*) is formed as follows: A full-length cleat, 1/4 in. wide, tapering from 1/2 in. deep at the head-motion end to a feather edge at the concentrate end is laid along the tailing side with the lower edge in the same plane as the outer face of the outer deck timber. The shortest riffle cleat, about 4 ft. long, 1/4 in. wide, and tapering from 1/4 in. deep at the motion end to a feather edge, is placed parallel to the first and partly under the feed box. Forty-four other riffles of the same width, spaced on about 1 3/8-in. centers, are then placed between the first two. Their heights at the motion end are graduated between those of the first two cleats; they terminate along a diagonal line joining the thin ends of these cleats, and each is tapered gradually to a feather edge at this line. Brads penetrating at least 3/8 in. into the wood of the deck and spaced on about 6-in. centers should be used to hold down the cleats. In placing NEW LINEOLEUM and riffles on a deck, first allow the linoleum to flatten out of its own accord in a warm, dry place, then set it on a clean, smooth deck with an overlap on the tailing side and concentrate end of about 1/4 in. Tack lightly in place. Lay the longest riffle, mark the location of the shortest and of the diagonal line, then lay the remaining riffles, working upward from the tailing side, using a template to obtain the desired spacing. Finally tack down the edges of the linoleum and place quarter-round strips on the feed side to exclude water and pulp from the under side. Puffs will usually disappear after a few days' use and should not be tacked down. Fig. 52 shows four types of riffling.

Tables are built both right- and left-hand. RIGHT-HAND TABLES have the feed box and drive pulley at the right when the observer stands at the head-motion end and faces the table; LEFT-HAND, *vice versa*. In a large installation, about 10% of floor space and some piping and laundering can be saved by mounting a right- and a left-hand table close together, leaving an aisle between every two pairs.

FEED AND WASH-WATER BOXES are open-topped troughs carried along the high side of the table deck. Feed box is attached to the deck and extends about one-quarter to one-third the length from the head-motion end. Wash-water box extends the remaining distance along the table and, in the modern types, is also attached to the deck. Egress is by holes at the back (upper side) of the boxes and is regulated by fingers buttoned over the holes. The shaking motion keeps the heavy portion of the feed sufficiently in suspension to cause it to distribute and flow. Water is introduced by hose through a hole in a cover board over the center of the water box, thus preventing splashing. An open water box is superior to perforated pipe as it permits ready cleaning of clogged exit holes.

The old method of distributing wash water along the concentrate end by a shallow cantilever trough with drip holes near the lower corner has been discontinued. The best method of keeping this end of the table washed is to cut the end back diagonally by shortening the tailing side 3 to 6 in., or water discharged from the feed-side water box may be diverted in part to the concentrate end by a proper arrangement of small cleats tacked to the unriffled surface.

SEPARATION OF CONCENTRATE FROM MIDDLING should always be made on the concentrate end where the movement of the discharging stream is parallel to the splitter edge. The tailing-middling split can be brought to the end also, with considerable advantage in some cases, by bringing the line of termination of riffle cleats up to about the quarter-point on the concentrate end. Fingers fastened to the deck are sometimes used to do away with constant tilting of the deck or shifting of the product pans. A finely corrugated discharge lip on the concentrate end aids in effecting a clean cut between products.

Performance. Table 51 is a summary of operations of Wilfley tables on lead, zinc, copper, and precious-metal ores. Table 52 shows the performance of tables on several different grades of classified feed at NEVADA CON. COP. CO. In most mills the Wilfley table is used on sandy feed, making clean concentrate and a tailing to be reground and retreated

e Feed, second spigot of classifier.

At New Jersey Zinc Co., Franklin mill, two identical groups of 20 Wilfley No. 9 tables are used for separating <28-m. willemite from calcite. Feed is deslimed in 8-ft. Allen cones, the sands of which are subdivided by two 20-spigot Pellett classifiers (Sec. 8, Art. 11), each spigot feeding a separate table. Tables are single-deck, 12 ft. 8 in. long on the feed side, 12 ft. 10 1/2 in. on the tailing side, by 5 ft. 2 in. wide at mechanism and 4 ft. 7 5/8 in. at concentrate end. Cover is 3/16-in. rubber, with pine riffles. Speed of all, 315 s.p.m. Length of stroke: 7/8 in. on tables 1 to 4; 13/16 in. on Nos. 5 to 8; 3/4 in. on Nos. 9 to 12; 11/16 in. on Nos. 13 to 16; 5/8 in. on Nos. 17 to 20. Feed, containing 75% water, ranges from 0.25 to 0.50 ton solids per hr. per table, and assays 27% Zn; tailing, 1.25%; concentrate, 47% Zn; all middling returns to tables *via* the classifier. Wash water per table, 600 g.p.h.; power, 1 hp. One man attends 20 tables, adjusting stroke, tilt, and water. Average working time lost, 3% for minor repairs; more important changes are made during an idle shift. At Calumet & Hecla, conglomerate mill, standard linoleum-topped, wood-riffled, single-deck tables account for about 42% of the total copper output of the plant, Woodbury jigs (Art. 6), flotation, and ammonia leaching contributing most of the remainder (*IC 6364*). The tables serve a variety of purposes: (*a*) In each of the 11 primary crushing units, 2 tables receive the hydraulically classified slime from 2 Woodbury jigs, producing finished concentrate, tailing for flotation, and middling for retreatment on a third table which yields only concentrate and tailing. (*b*) In each of the same units, 2 tables take all 5 hutch products of 2 jigs, making concentrate, middling to be cleaned on a third table (as above), and tailing for regrinding. (*c*) In each of 24 recrushing units (treating the last-mentioned tailing together with those from the jigs) 5 tables, fed direct from a Hardinge pebble mill, make tailing and a rough concentrate, the latter yielding finished concentrate (and tailing) on 2 additional tables; all tailings from these 7 tables go to flotation and leaching. Table 53 gives screen assays on the work of tables in groups *b* and *c*, above,

a Averaging 0.87% Cu.

as in 1929. At Copper Range Consol. Freda mill, each of 35 Wilfley tables (made in company's shop) treats 2.4 t.p.h. of <7/32-in. crusher product sized as in Table 54. Deck is 14 ft. 9 in. long, 6 ft. 1 in. wide at mechanism end and 5 ft. 1 in. wide at concentrate end; cover is Armadillo rubber 1/8 in. thick, with fabric back. The 27 (usually maple) riffle strips (terminating in standard fashion, Fig. 52, item *a*) are uniformly 1 1/2 in. wide, 5/16 in. high, and spaced 3/4 in. apart. The down-slope side of each strip is beveled from the centerline down to a thickness of 1/4 in. Each strip is terminated by a

separate tip 9 in. long, feathering to its end. Strokes, 1 1/8 in. @ 255 r.p.m. Water in feed, 66%; wash water (clear), 620 g.p.h. per table; power, 0.3 hp. One man attends 16 tables, adjusting feed, wash water, tilt, and length of stroke. Assays, % Cu: feed, 3 to 5; concentrate, 60 to 63; middling, 2.5 to 3.5; tailing, 0.4 to 0.7. Breakage in head motion is the chief cause of delays.

At MAGMA, treating a massive mixture of bornite, pyrite, and chalcopyrite (all carrying gold and silver) in a gangue of silicified diabase, 18 Wilfley No. 6 tables are used as roughers in advance of flotation, to which all of their tailings are subjected (*IC 6319*). Feed to tables is unclassified undersize of a Callow 14-m. screen, with 45% water; average capacity for solids, 1.75 tons per hr. per table (750 t.p.d. to the mill). Table concentrate comprises 43% of the total mill yield. Tables, 15 ft. long, 6 ft. wide at head, and 5 ft. wide at concentrate end, are covered with moderately rough linoleum, which lasts 18 mo.; full-length wooden riffles are 1/4 in. wide, 1 in. apart; concentrate end of deck is 1/2 to 3/4 in. higher than feed end. Speed, 240 @ 7/8-in. s.p.m. A 10-hp. induction motor drives a group of 6 tables by line shaft, with expenditure of 0.42 kw.-hr. per ton. Wash water, 480 g.p.h. per table. The ball-mill operator also attends to all 18 tables, adjusting only tilt and wash water to attain a certain limit of insoluble in the concentrate. Owing to metallurgical requirements, high iron is desirable. Ratio of concentration, 5.5 : 1. Table 55 presents additional data as of 1929. In 1939, average copper assays were reported as: feed, 5.07; concentrate, 9.90; tailing, 3.99%. At AMERICAN METAL Co., Shafter, Tex. (*112 A 704*), a siliceous and partially oxidized lead-silver ore, with occasional free gold, is treated on a battery of 11 standard Wilfley tables to extract as much as possible of the argentiferous galena before cyaniding. Of these tables, 3 are fed direct with <10-m. primary feed; 6 receive feed direct from tube-mill and deliver middling to 2 cleaning tables. All tables yield finished concentrate, while all tailing returns to tube-mill-classifier circuit and thence to cyanidation. Data in Table 56 refer to operations in 1929 as above described. Feed to the first 3 tables, containing about 50% of the total lead going to tables and diluted to 14% solids, averaged 32 t.p.d. Feed for the 6 tables in the tube-mill circuit was diluted only to 46% solids. Recovery of lead in concentrates from all tables was 32.8%, based on entire mill feed (157 t.p.d.) averaging 19.7 oz. Ag, and 2.5% Pb, the latter equally divided between sulphide and oxidized minerals. As reported in 1939, the mesh on the primary screen had been enlarged to 6. Standard 14-ft. tables have rubber decks and pine riffles. Speed, 260 @ 3/4 in. s.p.m. on the tables fed from screen, 5/8 in. on the others. Feed, 1.6 ton per hr. per table, carries 55 to 60% water; clear cyanide solution is used as

wash water. Assays, % Pb: feed, 1.0; concentrate, 50.0; middling, 6.0; tailing, 0.5. One man attends all tables; time lost, 6.1%, is due mainly to tube-mill repairs and power shortage. At SHENANDOAH-DIVES (*136 J 395*), treating 600 t.p.d. of complex Pb-Zn-Fe-Cu ore carrying Au and Ag, 3 Wilfley No. 6 tables in parallel come between a 6-m. trommel and a Dorr deslimer, all in closed circuit with a Marcy ball mill; tables extract a marketable concentrate, while also improving flotation recovery from the slimes by avoiding over-crushing. Both table surface and riffles are of Linatex. Speed, 260 @ 3/4-in. s.p.m. Table 57 (*PC*) records performance of these tables during a typical month when they extracted 112.9 tons of concentrate from 21,485 tons of ore. Flotation tailing, after desliming and hydraulic classification, passes to 2 other Wilfley No. 6 tables which make final tailing and a >42-m. middling; latter is recrushed in circuit with another Wilfley recovering an Fe-Au concentrate. At SUYOC CONSOL., Philippine Islands, a small (7-ft.) double-deck table for cleaning corduroy-blanket concentrate, is fed by hand, 8 hr. per day. Lower deck is 48 in. wide at feed end, 41 in. wide at other; corresponding widths of upper deck, 24 and 30 in.; linoleum cover and pine riffles. Speed, 240 @ 1/2-in. s.p.m. Concentrate contains free gold, galena and other sulphides, and tramp iron; it is treated, in batches, by pan amalgamation.

Table 57. Work of Wilfley primary tables, Shenandoah-Dives mill

Insol., %...	....	1.8	....

Capacity. On zinc-sulphide ores the tonnage treated ranges from 14 tons per 24 hr. on 0.8-mm. feed to 100 tons on 2.5-mm. feed; separating willemite, with closely classified feed, capacity ranges from 6 tons with 0.4-mm. material to 12 tons at 2.3-mm. On lead ores, when both clean concentrate and finished tailing are sought, capacity ranges from 10 tons on 0.5-mm. feed to 45 tons on 2-mm. size. Capacity treating native-copper ore all through 0.6-mm. and containing 40% slime is 15 to 25 tons per 24 hr. when making clean concentrate and finished tailing. Treating porphyry-copper ore (operation now obsolete, but data useful for estimating) the capacity on material through 0.6-mm., when making finished concentrate and tailing, is 14 tons per 24 hr.; treating rougher-table concentrate capacity is 45 to 75 tons and when roughing <2.5-mm. feed, 200 tons. Separating auriferous pyrite from siliceous gangue, capacity is about 25 to 30 tons per deck on 1-mm. sands, falling to 10 tons on 0.1-mm. sands and rising to 50 tons on 2-mm. material.

Table 58. Sizing-assay test of Wilfley-table tailing, Anaconda Copper Mining Co.

0.07	14.98	0.14	9.08
<0.07	3.10	1.25	17.13

Size of feed, with ores, rarely exceeds 2.5-mm. Wiggin (*46 A 232*) determined that 0.025-mm. was the smallest grain that could be saved with ANACONDA ore. The coarser, sandy portion of 200-m. slime is readily saved. Table 58 is a sizing-assay test of ANACONDA table tailing when a roughly deslimed feed was being treated. Table 59 gives similar results at RAY CONS COP. Co., except that the feed was not deslimed. Here maximum loss of copper and maximum assay occur in the finest size; there is also a relatively high copper loss in the coarsest sizes.

Total	99.8	99.9	0.60	0.58	100.0	100.0

Speed and stroke. Speed ranges from about 230 to 280 s.p.m., being close to 250 in the majority of mills. Length of stroke averages close to 3/4 in. Within the range of practice presented, no distinct relation between stroke length and speed is established, but in general a short stroke corresponds to a high speed and *vice versa*.

Wash-water consumption ranges from 1.5 to 40 g.p.m., the high figure being in roughing service and the low corresponding to a very dilute feed pulp. Average consumption for average service is about 8 g.p.m.

Slope varies with size of feed, specific gravity of minerals, character of products desired, and the place that the products are split, as well as with the quantity of wash water. The usual slope with fine feeds is from 1/4 to 1/2 in. per ft. and 3/4 to 1 in. with coarse feeds. When roughing, the slope may be as much as 2 in. per ft.

Power. Actual power consumption under average load is close to 0.6 hp. with a usual installation of between 0.75 and 1 hp. per table. For individual drive, 1 1/2-hp. motor is standard.

Lost time is very small and is principally due to shutdowns for replacing deck covering and repairing or renewing riffles. In large mills, it is customary to maintain a reserve of fully equipped decks, with which to replace disabled decks with minimum delay. A carriage (*138 #9 J 44*) facilitates such replacements. Mechanism difficulties usually correspond to high tonnages and long stroke or to attempts to run double decks with the standard head motion (see Garfield-table head motion, Art. 20).

Operating adjustments available on the standard table are length of stroke, tilt, wash water, location of product splitters. In small mills where irregularity in feed conditions is frequently the rule, control of all of these is necessarily left with the operator. The tendency in large mills is to limit operator's adjustments to tilt and wash water, while in some mills tilt is not adjustable and the operator controls wash water only. In some plants splitters are fixed in position and products must be brought to the proper points by shifting their position on the table deck by changing tilt and wash water. It is much better to have movable splitters and to take care of all minor shifting of the product streams by moving the splitters, leaving water and tilt as nearly undisturbed as possible. Recent models, with individual drives, provide for speed adjustment, but most operators prefer a fixed speed, once this has been satisfactorily ascertained.

Comparison with other machines. For results of competitive tests with other tables, see the other tables.

As a result of a competitive test with a fine jig at BUNKER HILL & SULLIVAN, Caetani concluded (*3 MM 54*) that the Wilfley table had twice the capacity of the jig, made a higher recovery, and required less skilled labor and less water, power, and repairs. The table made a slime separation that a jig fails to make and there was less fall of material in passage through the machine. Jig concentrates were richer and the middling contained less free mineral. Tailing assayed about the same in both cases but the coarse part of the jig tailing was lower grade while the fine part was of higher grade than the Wilfley.

Buss table and **Ferraris table** have the deck frame supported on a number of lath-shaped ash or hickory strips, pivoted at the lower end and standing inclined toward the motion end about 15° from the vertical. The head motion is a simple eccentric. On the forward stroke particles in contact with the table deck move forward and upward with it; on the reverse stroke the particles continue to move forward but, by reason of the fall of the deck, are out of contact with the deck during a part of their forward travel. The result is that forward travel is much more active than on tables with purely rectilinear motion. Height and taper of riffles, speed, stroke length, power and water consumption, and capacity are about the same as on the Wilfley table. Riffling plan differs slightly.

Overstrom table has similar deck support but the lath springs are set so that the long transverse axes center at a point on the centerline of the head-motion shaft extended 50 ft. beyond the feed side of the table, which gives the deck a curvilinear motion. Riffle cleats are curved to make them substantially tangent to the deck motion at all points in their length. Head motion; see Fig. 60. Decks 6×15- to 9×36-ft.

17. BUTCHART TABLE

Description. This table (also called NATIONAL TABLE) is a rectangular-deck, full- or part-riffled table, differing from those previously described in that the riffles are bent

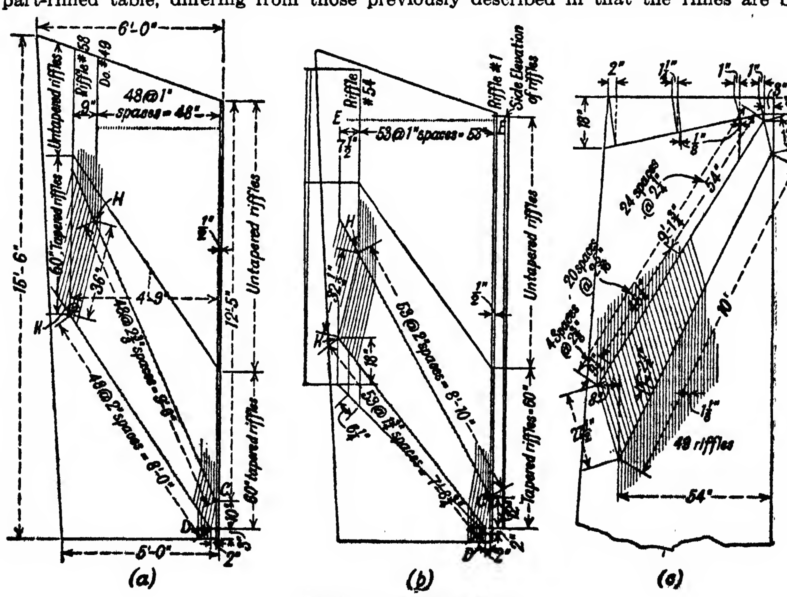

FIG. 53. Butchart riffling.

diagonally toward the feed side about along the line of the "Wilfley diagonal" and run in this direction for a few inches, where they terminate or are again bent back substantially parallel to the tailing side. Diagonally terminated riffling is used for cleaning; full-length riffling principally for roughing but also for cleaning. The WAVE in the riffles along the diagonal line is claimed to effect a rotary vanning motion that aids in bringing gangue to the surface of the beds in the riffles where it can be washed away. Fig. 53 shows plans of three forms of Butchart riffling. Either of types *a* or *b* may be changed to full length by continuing the riffle cleats to the concentrate end in a direction parallel to the tailing side. Probably most Butchart riffling is mounted on Wilfley mechanisms, but a Butchart head motion (Fig. 54) of the toggle type is built.

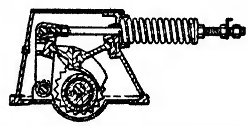

FIG. 54. Butchart head motion.

Effect of full-length riffling is shown in Fig. 55. The coarsest heavy mineral discharges highest up on the concentrate end and there is a uniform decrease in size of heavy mineral in the concentrate as the tailing side of the table is approached. The gangue sizes, on the other hand, are distributed as on the Wilfley table. This arrangement of discharging grains is due to the fact that after stratification, which takes place as shown in Fig. 46, although the light minerals are washed away as on the Wilfley table, the heavy minerals receive support from the riffles the full length of the deck, are not subjected to film-sizing, and the only effective force acting to cause size segregation is eddying in the riffles. The eddying water lifts the finer particles more readily than the coarse and these particles are, therefore, carried over the riffle cleats and down slope, while the coarse particles travel along to the end of the table. The result is to spread the product bands at the discharge edges of the table and permit much closer and cleaner splitting than is possible with diagonally terminated riffles. This is particularly true of the concentrate-middling split. On the other hand, the full-length riffles support fine gangue and carry it toward the concentrate end, with the result that more water must be used to get clean concentrate than on a table with partly plane surface, and there is more fine clean gangue in the middling.

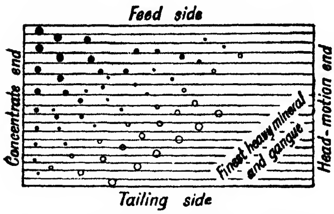

FIG. 55. Distribution of minerals at discharge end of a shaking table riffled full length.

Performances at several mills are given in Table 60.

In the BROKEN HILL SOUTH mill, erected 1928 (*88 Aa 247*), 28 Butchart tables treat tube-mill discharge deslimed in Dorr C-20 classifiers, of which each feeds 7 tables at 1.57 t.p.h. per table, including 0.24 ton of returned middling. The table is 15 ft. 8 in. long on the feed side, 13 ft. 9 in. on discharge side, by 5 ft. 11 1/2 in. wide at the feed end, and 5 ft. at discharge end. Complete deck weighs 705 lb. Oregon-pine riffles, 1/4 in. wide and 1 in. apart, are 1/4 in. high for 7 1/2 ft. from feed end, tapering to 1/16 in. in the next 5 ft., and terminating at the diagonal intersection with cleaning plane. The last segment of riffles curves upward toward the feed side. Linoleum cover has a maximum life of 16,640 running hr.; riffles at feed end, 8,152 hr.; with moderate repairs at this end, riffles will last as long as linoleum. Feed is delivered by a vertical pipe, discharging into a box with chilled-iron bottom and holding a bed of ore to reduce wear. Speed, 293 @ 7/8-in. s.p.m. Each row of 7 tables is driven through countershaft by a 7.5-hp. motor. Floor, 104 × 77 ft., slopes 2 in. per ft., and supports steel-lined concrete launders. Middling returns to the Dorr classifiers; tailing is further reduced to flotation size. Operating results over latter half of 1931 are in Table 61.

<200	2.7	5.81	2.2	3.8	2

Maximum size of feed that can be handled depends upon the type of riffling. In roughing service, with tables riffled full length, the maximum size of feed is probably about 3/8-in., but with such coarse feed, while a clean coarse concentrate can be taken, it is difficult, if not impossible, to make a satisfactory separation of middling from tailing. In finishing service, with diagonally terminated riffles, the maximum size that can be satisfactorily treated is about the same as on a Wilfley table, *viz.:* 2- to 2.5-mm. Minimum size is the smallest that will settle in the cross-water current and will therefore be smaller the smaller the maximum-sized particle of feed. At the Bonne Terre mill of ST. JOSEPH LEAD Co., general mill concentrate was deslimed at 100-m. and the fines thickened and treated on a Butchart table. The concentrate assayed 80% Pb.; 95% passed a 200-m. screen; tailing assayed 6% Pb. When coarse feed is treated it is necessary to have fine sand present. Attempts to enrich jig lead concentrate on the table failed until sandy table concentrate was added.

Riffling is varied according to the character of service and size of feed. Full-length riffling is used principally in roughing, but may be used also for finishing, especially when the ratio of concentration is low; diagonally terminated riffles are used for cleaning. Riffle cleats are usually 1/8 in. high at the concentrate-discharge end, tapering from about 1/2 in., but when the feed is coarse, ratio of concentration

low, or tonnage exceptionally high, the taper may be from 1 in. to 3/8 in., in order to provide concentrate-carrying capacity. With such deep riffles at the concentrate end, they are usually given a slight curve downhill near the end in order to keep sufficient water along this end to prevent banking. The average RISE of RIFFLE CLEATS in the "wave" section is 1 in. in 4 in. of run parallel to the tailing side. The steeper the rise the cleaner the concentrate, other conditions being constant. Riffle cleats in roughing service or with coarse feed are usually of hard wood, oak or maple preferred; in cleaning, sugar-pine cleats are satisfactory. Life of oak riffles is three times that of pine.

Linoleum is the usual DECK COVERING, but soft rubber (old vanner belts) has been used at the Morenci branch of PHELPS DODGE and in the SOUTHEAST MISSOURI lead district. Concrete has been used at Bonne Terre mill of ST. JOSEPH LEAD Co. Concrete mixture was 2 of sand (2-mm.) to 1 cement; it was laid on linoeum flush with the tops of riffle-nailing cleats 3/16 to 1/4 in. high and was given a steel-trowel finish. Life of linoleum covering is 6 mo. to 3 years, depending upon the size of feed; rubber has a longer life, but new covers cost three to four times as much as linoleum.

Capacity on 2- to 3-mm. feed in roughing service is from 100 to 200 tons per 24 hr. which is about the same as that of the Garfield table (see Art. 20). In finishing work on 1.5- or 2-mm. feed the capacity on lead ores is from 30 to 65 tons per 24 hr. and in cleaning rough copper concentrate, through 8-m., ranges from 40 to 75 tons. Cole (*51 A 405*) reports 80 t.p.d. treating deslimed Hancock-jig concentrate, <3/8-in., at MORENCI, lowering the percentage of insoluble from 30 to 15.

Speed and length of stroke. The usual range in speeds is from 240 to 280 s.p.m. and average length is close to 1 in. The examples cited do not show any distinct relationship between character of feed and the stroke, nor between speed and stroke length, but in general the rule applies that coarse feeds require longer and slower strokes than fine feeds.

Wash-water consumption averages close to 10 g.p.m.

Lost time is estimated as close to 1% on the average and is due principally to replacement of deck covering and riffling.

Attendance. Operators control tilt and wash water in all mills reporting and at MORENCI also control feed rate to a certain extent. The relatively low figures under "machines per man" in Table 60 are probably due to the fact that no more tables were installed calling for attention. Butchart riffling, particularly full-length, spreads the concentrate and middling bands out into wide fans which change position only slightly with changes in feed rate, hence control is easy and attendance should be small.

Butchart *vs.* Wilfley. Cole (*51 A 405*) reports the following 4-day test at MORENCI.

Feed, deslimed rougher tailing after regrinding to pass 1.5-mm. Results as in Table 62, test A. Test B in the same tabulation shows the results of treating roughly deslimed 20-m. feed on a Butchart table with special deep riffles. On the bases of metallurgical results alone the advantage, if any, in these tests was with the Wilfley table on account of the fact that tailing was too high grade to discard in both cases and the operations must therefore be judged on the concentrate taken out; but capacity and water consumption and, necessarily, power, labor, and maintenance were all in favor of the Butchart. Results of similar competitive work in treating lead ores in SOUTHEASTERN MISSOURI were the same, the Butchart table yielding the same tailing and concentrate when treating 50 to 60 tons per 24 hr. of deslimed 2-mm. feed as the Wilfley table yielded when treating 20 to 25 tons (*57 A 350, 429*). In analyses of operation in both these fields the Butchart table was credited with elimination of all classification other than rough desliming, but this saving in treatment was rather due to the introduction of flotation, which removed from the tables the burden of making finished tailing.

Butchart table *vs.* jigs. Table 63 presents the results of a competitive run between a Butchart table and a Harz jig at the DETROIT COPPER Co. plant on primary feed passing a 7-mm.

18. CARD TABLE

Description. This table differs from the Wilfley principally in that the riffles are cut into the deck and are triangular instead of rectangular in cross-section (Fig. 56). The cross-section of the riffles increases from the head-motion end to a maximum along a diagonal corresponding to the termination of standard Wilfley riffles, then decreases to nothing at the concentrate end. On tables for fine feed the riffles contract from maximum section at head-motion end to disappearance at the diagonal line. Riffles for coarse feed are about 2.5 in. apart, $^5/_8$-in. maximum depth and $^1/_{16}$-in. minimum.

Fig. 56. Cross-section of riffling on Card table.

Head motion is shown in Fig. 57. *A* and *C* are fixed pins and *B* a fixed toggle block. The motion of crankshaft *G* is transmitted through the pitman and toggles to lever arm *D*, thence by connecting arm *F* to lever *H*, the upper end of which *E* draws the table deck back against spring *S*. The forward stroke is impelled by spring *S* but controlled by the mechanism. Length of stroke is varied by changing the position of pin *P* in lever *D*. The deck motion is differential, of the same general character as the Wilfley, but has been found to give a sharper return stroke and thus affords greater capacity. The deck is roughly 5 1/2 × 16 ft. There is a line of flexure in the deck along the diagonal from the feed corner, which permits the slime corner to be raised or lowered out of plane with the other half of the deck. When the deck is tilted up, crowding occurs along the diagonal of separation. The deck is usually set horizontally lengthwise. The Card table has been best known in the Bunker Hill & Sullivan lead-silver mill (*3 MM 50*), in the lead-zinc mills of Broken Hill, N. S. W. (*28 MM 8; 28 IMM 14*), and at a few mills in central and southwest Colorado treating complex sulphide ores (*Richards, IV*); it was particularly noteworthy for its ability to carry overload without serious loss of efficiency. It was not employed in any of the mills from which reports were received in 1939.

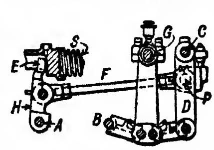

Fig. 57. Head motion, Card table.

19. DEISTER-OVERSTROM DIAGONAL-DECK TABLES

Description. Decks of these tables are rhombohedral, with rectilinear motion in the direction of the short diagonal, which is also the tilting axis and the direction of all riffling.

Feed is distributed for about one-half (sometimes more) the length of the upper edge, tailing discharges over the lower edge, and concentrate (also middling, if desired) over the end opposite the mechanism. The entire deck area lies in one plane, and a portion of it (variable with type of service) is unriffled.

The asserted ADVANTAGE of the rhombohedral as compared with a substantially rectangular shape is argued on the basis of Fig. 58. When treating a sized or classified feed on a rectangular deck, the area of table actually occupied by ore takes the form of a diagonal band from feed to concentrate corners, approximately bisected by the line *CD;* with a given setting of table, feed, and water adjustments, the width of this band depends primarily upon depth of riffles, shallow riffles tending to widen and deep riffles to narrow the band. An unsorted feed travels in a wider band; its finest components are largely discharged between points *B* and *J* (see also Fig. 45). On a rectangular deck, the rate of feed is limited to the amount that can be settled and stratified while passing over riffled area *ABDC*. The rhombohedral deck, with riffled area *CHBFG*, makes the additional riffled area *BFJ* available. All other things being equal, this added riffled area in the slime path will settle some material that would have been discharged by a rectangular table along the line *BD*. The rhombohedral deck should, therefore, treat a larger tonnage of a classified feed, or handle a longer-range feed than a rectangular table with equal tailing loss. Unriffled areas for cleaning are approximately equal (*GFK vs. CDE*). Shallow riffles on the Deister-Overstrom decks spread the band and facilitate segregation.

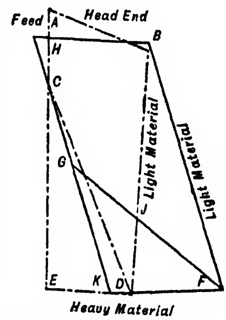

FIG. 58. Diagonal *vs.* rectangular deck.

The argument is plausible. Certainly the opportunity for catching and bringing material to the cleaning plane is greater on the diagonal deck, and there is also a proportionately longer line of riffling on the line of cross-water flow below the emergence of any given riffle at the cleaning plane on the rhombohedral than on the diagonal deck. Hence there is more chance to catch heavy mineral scoured off the cleaning plane and re-present it.

Construction. Table base is a pair of parallel longitudinal 9-in. channels, tied on bottom by sole plates at middle and ends. Longitudinal slope is adjusted by shimming under the concentrate end. Head motion and a rocker arm are mounted at one end, and another rocker and a helical compression spring at the other. Straddling the upper edges of the channels are 3 saddles with circular depressed upper surfaces by which the tilting sub-frame is supported; the rocker arms carry no weight. The sub-frame, of braced structural steel, rests in the saddles at 3 points on its diagonal line, the 2 outer corners rest on blocks of which the elevations are adjustable by oppositely facing wedges manipulated through hand-wheel and spur gearings. Maximum tilt on the standard tables is 6°; on the special "High-tilt" table, 12°. On its upper side, at the 4 corners and 2 mid-points of its sides, the sub-frame carries 6 slide blocks, each depressed in a receptacle containing oil. The deck is built of cypress, in strips laid diagonally to its framework; each of 3 light structural-steel cross members has 2 slide blocks corresponding in position with those on the sub-frame. The main longitudinal member of the deck has a socket at each end to engage the upper ends of the 2 rocker arms between which the deck is held constantly in tension. Deck is tilted without loosening connection with the head motion. Deck is covered with linoleum or rubber (white or variously colored). Riffle cleats are pine, hardwood, or rubber, the last cemented to a rubber cover.

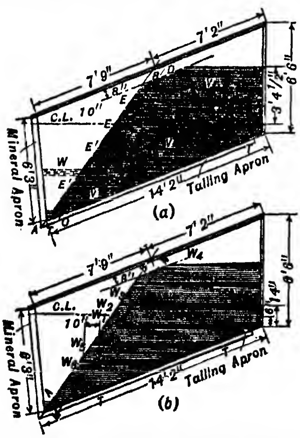

FIG. 59. Riffling of Deister-Overstrom table. (*a*), sand table; (*b*), slime table.

Riffling of the standard No. 6 tables is characterized by a large number of shallow riffles, interspersed by somewhat higher strips which provide pools to permit settlement of fine grains. Fig. 59, item *a*, shows the riffling of the SAND TABLE, recommended for feed up to 4-m. The tailing riffle strip *TT* is $^1/_4$ in. high at head end, feathering at *A*. The "body" riffle strips *V*, $^1/_4$ in. wide and spaced 1 $^1/_{16}$ in. c-c., are uniformly $^1/_{16}$ in. high from head end to the line *CD*, tapering for 10 in., and feathering on line *AB*. The tapered strip *E*, on the centerline, is $^1/_4$ in. high at head end, tapering uniformly to feather on line *AB;* other tapered strips *E'*, taking the place of every eighth body riffle, have the same pitch as *E*, that is, their head ends are proportionately reduced in height. The strips *W*, $^1/_{32}$ in. high, optional as to number and position, may be added to assist a two-mineral separation. The standard No. 6 SLIME TABLE (Fig. 59, item *b*) differs from the sand table only in the riffling. The tailing strip *TT* is 2 in. wide at head and $^1/_4$ in. wide at concentrate

end; it tapers from 1/2 in. high to feather. The master strip W_1 is 3 in. wide at head and 1/4 in. at concentrate end, tapering from 1/2 in. high to feather on line AB; the other "wave" strips W_2, W_3, etc., spaced 14 in. c-c., have the same pitch and tapering width as the master strip. All of the wave strips are triangular in section, high in the middle and beveled to feather edge on both sides; this is believed to reduce disturbance in the pools. The first 2 strips x below a wave strip are uniformly 1/32 in. high to the line MN, tapering thence for 10 in. to feather on AB. All other strips are 1/16 in. high from head to the line MN, feathering to AB; they are spaced 1 1/16 in. c-c.

Overstrom head motion (Fig. 60) comprises the eccentric shaft a; the pitman b; toggle c, bearing at one end on a pin d attached to the pitman, and at the other against the fixed pin e carried by the adjustable sliding block f; shifting of the latter varies length of stroke between 5/16 and 1 3/8 in. The two-armed yoke g encircles the pin d and is attached at the other end, by the connecting-rod h, to the rocker arm actuating the table. A continuous state of tension is maintained in the yoke g by a compression spring placed under the concentrate end of the table and opposing the backstroke of the deck, the latter coinciding with the upstroke of the pitman. In case of accidental release of tension, the guard k prevents the toggle from falling. The oil pump j lubricates the pitman head, while main shaft bearings are chain-lubricated from separate reservoirs. The entire mechanism is enclosed in a cast-iron housing.

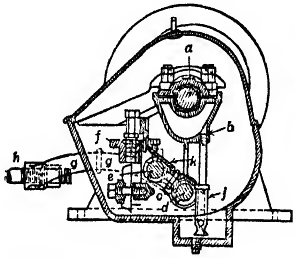

Fig. 60. Overstrom head motion.

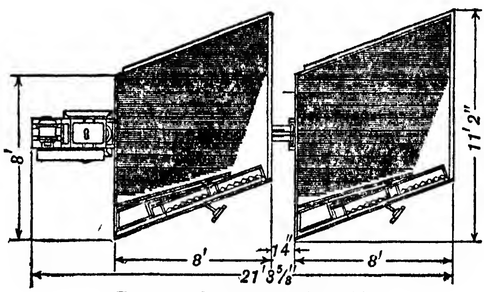

Fig. 61. Concenco duplex table.

Concenco head motion is designed for large capacities or uncommonly coarse feeds; it is interchangeable with the Overstrom head motion and may be applied to any of this manufacturer's tables. It is identical in principle with the Overstrom head motion, but is more rugged, especially as to the pitman; the eccentric runs on SKF roller bearings and the driving shaft on ball bearings, all lubricated by circulating oil. Either head motion may be driven by line-shaft belt or by individual motor; operating power, 1/2 to 3/4 hp. for the Overstrom, 1/2 hp. for the Concenco on a No. 6 table; when individually driven, a 2-hp. motor is recommended.

Concenco No. 10 Duplex table (Fig. 61) was designed primarily for coal, gravel, and similar coarse materials, but is applicable to any ore which can be treated at coarse size and high rate, or where tonnage does not require two full-sized tables.

Construction is similar to that of the No. 6 table, except that each deck slides on 4 instead of 6 bearings. The two rocker arms are connected by a bar with pin joint at each end. The Concenco head motion and 3-hp. motor are standard equipment.

Performances. In the Colquiri mill of Cia. Minera de Oruro (see Sec. 2, Fig. 152) diagonal-deck tables serve the following purposes: (a) 6 tables treat fine sands, each table fed from a separate classifier spigot (Table 64); tailing analysis is given in Table 65. (b) 8 slime tables treat the thickened slime from the above sands; 3 tables each fed from separate cone settlers in parallel for the heavier fraction, and 5 fed at 25 t.p.d. each, from a 50-ft. Dorr thickener, which is fed overflow from the above cones and

a Included with next size.

also receives some coarser material from another source; analyses of feeds are in Table 66. (*c*) 8 slime tables retreat middling from the preceding group; (*d*) 4 slime tables retreat middling from the group (*c*) tables (Table 67); (*e*) 2 parallel tables treat the pyrite-impoverished residue from the final cleaning flotation cells (which retreat concentrates from all the preceding tables) and yield 25 t.p.d. in 2 grades of finished tin concentrate; Table 68 shows the composition of the richer product. All tables have linoleum decks and wood riffle strips. Speeds, r.p.m., of the several groups are: (*a*) 282; (*b*) 286; (*c*) 288; (*d*) 293. Power, 1 hp. each table. One man attends 6 tables, adjusting wash water and product cuts.

The CHAUPI mill of Cia. Minera del Cerro de Potosí, Bolivia, has 76 No. 6 diagonal-deck tables, 50 for sands, 26 for slimes. Sand-table feed is deslimed in all cases, and usually hydraulically classified; that for slime tables is somewhat imperfectly classified in hydraulic cones, or is merely settled slime or an unfinished product from a preceding table or flotation cell. Table 69 gives sizing analysis of classified feeds to a group of four sand tables; tabled slimes are usually about 95% <200-m. All tables yield concentrate, subject to final flotation of pyrite, but only the finer ones make tailing. Tables are decked with linoleum or rubber, with wooden riffle strips. Table 70 compares typical operating data on a sand and a slime table.

feed, 0.34 oz.; concentrate, 20.36 oz., tailing, 0.11 oz. Strokes, 290 @ 3/4 in. per min.; tilt, 3°; end slope, 1/16 in. per ft. A BARITE MILL at Cartersville, Ga., which makes the high-grade product on jigs, uses Deister-Overstrom tables to make a concentrate assaying about 90% $BaSO_4$ with no limit on iron, which is pulverized and sold for oil-well drilling mud (*148 A 277*). Table feed is deslimed, 6-m. roll product, and includes hutchwork from jigs; assay, 28 to 30% $BaSO_4$; dilution, 40% solids. Fourteen roughers make concentrate and tailing (5 to 12% $BaSO_4$); also middling, which is classified and fed to 8 cleaning tables. These make concentrate and return middling to the classifier. All tables have rubber decks and riffles. Strokes, 250 per min., are 1-in. on coarse, down to 5/8-in. on the finest table.

a Other constituents: 0.7% Zn; 11.3% Fe; 2.0% insol.

Capacity is 2.5 tons feed per hr. per table. Another mill in the same district is reworking <12-m. sand and slime from an old waste dump containing 20% or more of free and recoverable barite (*PC*). Classified feed goes to 8 No. 6 primary tables, of which the middlings are retreated on 4 similar tables. Combined output is about 3 t.p.h. of concentrate which, after eliminating iron and manganese magnetically, averages 94% $BaSO_4$. At a Florida PHOSPHATE mill (*PC*) a No. 6 diagonal-deck was run parallel with a Plat-O table on agglomerate feed (Sec. 12, Art. 30). Results are given in Table 71. Feed was 2 long tons per hr. to each table, and assayed 33.1%, B.P.L., 59.3% insol.

T. L. HERBERT & SONS use 7 No. 7-C diagonal-deck tables for shape preparation of construction SAND and GRAVEL from material dredged from the Cumberland River at Nashville, Tenn. (*36 # 8 RP 60; 37 # 11 RP 26*). The tables are 7 ft. 10 in. wide by 17 ft. long. Each is divided by a transverse partition into 2 separate concentrating areas, each having its own feed and wash-water box; concentrate from the head-end area drops through rectangular slots in the deck close to the partition. Decks are covered with rubber, and rubber riffle strips are nailed. Adjustments are given in Table 72. Capacity of a gravel table, 25 t.p.h.; of a sand table, 18 to 25 t.p.h. Each table is driven, through V-belt and Overstrom head motion, by 3-hp. squirrel-cage motor, drawing about 1 1/2 hp. Wash and feed water for whole plant, about 3,000 g.p.m.

WEST-LAND SECURITY Co., Tarbutton, Tex., uses 10 No. 6 diagonal-deck tables for purification of GLASS SAND at the rate of 10 tons of finished product per hr. for the plant (*PC*). Raw sand is 98% <28-m. and contains 0.132% Fe_2O_3, of which the larger part is in material coarser than 20-m. Table feed is <28-m., deslimed at 100-m., and amounts to 83% of the plant feed. The tables reject 13.7%. Cleaned sand (69.3% of plant feed), analyzing 0.054% Fe_2O_3, 0.73% Al_2O_3, 0.065% TiO_2, is immediately suitable for some purposes but requires an acid wash (reducing Fe_2O_3 to below 0.015%) before it can be used for flint glass.

a Usually clear, except when dry season requires large use of reclaimed water.

b Adjusting only tilt and wash water; stroke fixed.

Feed-pulp consistency ranges from 60 to 80% water. In SOUTHEASTERN MISSOURI work it was found (*96 J 57*) that pulp consistency was an important factor in obtaining a proper bed on the table, and the best consistencies were 10 : 1 (by volume) for coarse feed, 12 or 15 : 1 for medium sands, and 15 or 18 : 1 for slime.

20. GARFIELD TABLE

This is essentially a Wilfley table with riffles carried straight across from head motion to concentrate end over the full surface of the table. It is used exclusively for roughing service.

Construction. When specially built and not merely a Wilfley table with modified riffling, the deck is made rectangular, 4 ft. × 12 ft., and the head motion, although of the same type as the Wilfley, is sturdier in order to handle the heavier pulp loads. The table is frequently double-decked, the additional deck carried about 8 in. above the regular deck on heavy cast-iron stanchions attached to the

a Test 1, 129 tons per 24 hr. Test 2, 91 tons per 24 hr. Test 3, 65 tons per 24 hr.

the line corresponding to the Wilfley diagonal, and extended thence to the concentrate side at uniform depth. The bottom face of the riffle cleats is beveled to allow the side faces to stand vertically at the steep inclination of the table. Riffle cleats are usually hardwood, maple or oak. Linoleum is the commonest deck covering but wears rapidly and in some mills cast-iron plates with riffles cast on are let in near the feed corner to take the excessive wear at this point.

Performances are given in Table 73. Average capacity on <2-mm. feed is close to 125 tons per deck per 24 hr. with 245 to 250 @ 1-in. s.p.m. Table 74 shows the effect of tonnage on performance. This test shows maximum recovery of grains between 0.15- and 0.2-mm. at all tonnages with a sharp drop in recovery in the sizes below 0.15-mm. Low recovery in the coarser sizes is apparently due to included grains. The efficiencies of the respective concentrating operations, based on copper contained in free mineral, were 73.3%, 79.5%, and 82.8%. By increasing speed and length of stroke, CHINO raised capacity to 200 tons per deck without marked loss in recovery as compared with RAY results. Since tailing is to be reground in any case, such overcrowding of the table would seem justifiable. SIDE TILT in roughing is usually held constant and variations in feed conditions are taken care of by varying the WASH WATER. Consumption of wash water ranges from 3.5 to 12 g.p.m. Dirty water is usually used. POWER CONSUMPTION is slightly higher than for the Wilfley table on account of the heavier bed of solids on the table; power consumed by double-deck tables is 25 to 33% in excess of that for single-deck.

21. PLAT-O TABLE

Description. Deck is 14 ft. 2 in. long, 7 ft. wide at head and 6 ft. wide at concentrate end, made in three types which differ in contour and riffling according to the size of material treated. DECK CONTOUR is such that two or more plateaus are formed, of increasing

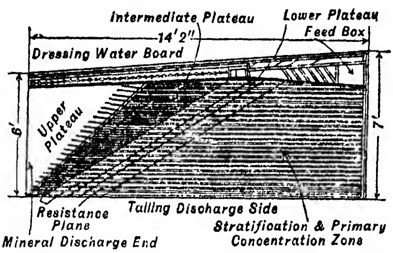

FIG. 62. Riffling of Plat-O table (Triplex; for coarse feed).

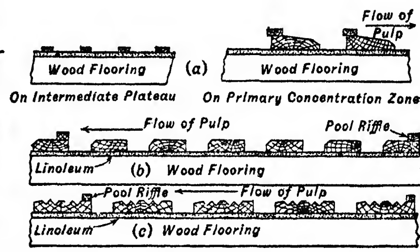

FIG. 63. Riffle cleats for Plat-O table.

elevation toward the concentrate end, joined by transversely diagonal slopes. Fig. 62 shows a 4-level table, for coarse feed; a 3-level form is used for ordinary sands, and a 2-level form for slime. Each plateau is $^1/_{16}$ to $^3/_8$ in. higher than its predecessor and is in the same plane as the tops of the riffle strips preceding it, the bottoms of the strips being tapered to fit the intervening inclined resistance planes. RIFFLE CLEATS (Fig. 63) are relatively wide and closely spaced. Item *a*, Fig. 63, is for the coarse-sand deck; *b* and *c* are used on the single-plateau tables; rectangular strip is sometimes used on the latter. Deck cover is either linoleum or rubber.

Head motion, Fig. 64, is totally enclosed, and submerged in oil to about half its depth. The roller *a*, free to rotate on its own center, is not concentric with the driving shaft and the pulley *b*. The oscillation thus produced is transmitted to the curved face of the rocker arm *c*, the outer end of which is pivoted on the pin *d*. The contact portion of this pin is also eccentric with its bearings; hence the position of the rocker arm may be shifted forward or backward (with effect on acceleration of stroke) by turning the pin (which can be done from outside). The toggle *e* transfers motion to the rocker *f*. The upper end of this rocker is slotted to receive a sliding block *g*, to which the connecting rod *h* is attached; length of stroke is adjusted by shifting position of *g* by screw *i*. Contacts are maintained, and forward stroke produced, by a helical spring hooked to the underpinning of the deck and adjustable, as to its tension, by a threaded rod connecting its other end to the foundation member at the concentrate end of the table. Manufacturer recommends strokes of $^{15}/_{16}$ in. @ 304 to 308 r.p.m. for the coarse-sand deck, $^{13}/_{16}$ in. @ 330 to 334 r.p.m. for the sand deck, and $^3/_4$ in. @ 346 to 350 r.p.m. for the slime table.

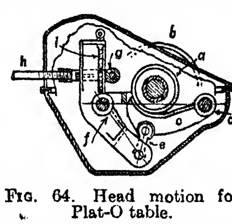

FIG. 64. Head motion for Plat-O table.

Rated capacities for ores are: Triplex, <$^3/_{16}$-in. feed, 50 to 150 t.p.d.; sand table, <30-m. sand, 30 to 40 t.p.d.; slime table, <80-m. feed, 15 to 30 t.p.d.

Suspended mounting. At one of the IDAHO-MARYLAND mills, Grass Valley, Calif., it became necessary to instal Plat-O tables on an elevated balcony, the floor of which had insufficient strength (*PC*). Each table, with its individual motor, was then mounted on a rectangular base composed of 2 longitudinal and 2 cross members, all of 12×12-in. timber. This base was suspended at 4 points by $^1/_2$-in. chains and $^3/_4$-in. eyebolts from 10×10-in. timber girders stiffened by 10-in. channels and resting on 10×10-in. posts about 20 ft. high, the latter standing on solid concrete floor. Oscillation of the hanging base, wholly unrestrained, was only $^1/_4$ to $^1/_2$ in.

Performance. Copper. At RAY CONSOLIDATED COPPER Co. a Plat-O rougher treating <5-mm. primary feed gave results shown in Table 75, indicating a consistent decrease in recovery and relative decrease in tonnage of concentrate with increase in feed tonnage. Grade of tailing is dependent rather on tonnage than on grade of feed while grade of concentrate is rather dependent on grade of feed and independent of tonnage treated. At the BURRO MOUNTAIN concentrator of Phelps Dodge Co. a Plat-O table treated flotation tailing deslimed in Allen cones at the rate of 39 tons per 24 hr. in a pulp containing 22% solids. Feed assayed 0.67% total Cu, 0.15 oxide; concentrate, 11.28% total Cu, 35% insoluble; tailing, 0.45% total Cu, 0.14% oxide. Recovery was 34.5% based on total Cu and approximately 42%, based on sulphide. At the same plant a roughing table treated 147 tons per 24 hr. of 14-m. feed in a pulp containing 45% solids. Feed assayed 2.14% total Cu, 0.26% oxide; concentrate, 14.66% Cu, 15.86% insoluble; tailing, 1.20% total Cu, 0.23% oxide. Recovery of total Cu was 47.8%, sulphide about 52%. At the Phelps Dodge MORENCI mill (*IC 6460*) in 1929, 40 Plat-O tables were treating primary ore (nominally <6-m.) at 143 t.p.d., producing concentrate at ratio of 1 : 50.64 and delivering entire residue to flotation. Assays in % total Cu: feed, 1.92; concentrate, 19.59 (or 20.2% recovery); tailing 1.56. Of the concentrate, 44% was 28~100-m., with 5.3% <200-m. Tables were driven by individual 1-hp. back-geared motors. Results of eight weekly test periods at ANACONDA roughing 8-m. feed are given in Table 76. Increasing speed in this test and placing cap riffles on top of the main riffles cut down the grade of tailing while increase in side slope reduced the amount of insoluble in concentrate. At INTERNATIONAL NICKEL Co., Copper Cliff, Ont., the entire <35-m. tailing from the

Zinc. Performance of a sand table in finishing service at the CONNECTICUT ZINC CORPORATION plant at Oronogo, Mo., is presented in Table 77. This table had the single plateau with thin riffle cleats extended to the concentrate-discharge end. The table was very stable in operation, handling fine material as well as coarse at a given setting and requiring but little attention.

Lead-zinc. At SAN FRANCISCO DEL ORO 1,100 met. t.p.d. is treated after ball-milling but without classification at <14-m. and 75% solids on 9 standard, single-deck Plat-O tables, from which the middling is re-treated on 2 tables of the same type; all tailings are further reduced to flotation size; table concentrate from feed assaying 7% each of Pb and Zn averages 72% Pb, and amounts to 40% of the lead in the ore (*137 J 397*). Such removal of coarse lead concentrate and subsequent mixing thereof with flotation concentrate aids in reducing moisture in filtration. Tailing averages 4.5% Pb. The tables have concrete decks and pine riffles. Speed, 260 @ 3/4-in. s.p.m. Power, 0.8 hp. per table; wash water, 10 g.p.m. One man attends all tables. At the MIDVALE plant, of U. S. S., R., & M. Co., flotation tailing is scavenged, after classification, on twenty 6×14-ft. single-deck Plat-O tables (*Q*). Feed is 37% <200-m., and carries about 80% water; rate of feed, about 6 t.p.h. per table. Deck has rubber top and wood riffles. Speed, 250 @ 1/2-in. s.p.m.; lateral slope, 1/2 in. per ft. Wash water, 600 g.p.h. Power, 1 hp. per table. Lost time averages 1%, due chiefly to head motion.

Tin. In the COLQUIRI mill of Cia. Minera de Oruro, 10 Plat-O 14-ft. tables treat classified feed, to a maximum size of 2-mm., at a combined rate of 185 t.p.d. (*Q*). Feed averages 3% Sn. See Sec. 2, Fig. 152 for flow-sheet. Tables 78, 79, and 80 give size and assay data. All tables have linoleum decks and wood riffle strips. The 10 primary tables operate at 254 r.p.m.; 5 secondary tables, at 279 r.p.m.; power, 1 hp. each. One man attends 5 tables, adjusting wash water and product cuts.

At the CHAUPI mill of Cia. Minera del Cerro de Potosí, Bolivia, four 14-ft. Plat-O tables in parallel with four Deister-Overstrom No. 6 sand tables treat deslimed hydraulically classified sands at a maximum size of about 20-m. (*Q*). See Sec. 2, Fig. 153. Feeds are identical with those for the diagonal-deck sand tables shown in Table 69 and average 5% Sn. Rate of feed averages 10 t.p.h.; water in feed, 70%. Concentrates average 35%; tailings, 0.7%; middlings, 8% Sn. Tables make 311 @ 3/4-in. s.p.m., requiring 1 1/2 hp. each. Wash water, about 500 g.p.h. One man attends 5 tables, adjusting only tilt and wash water (speed fixed).

Barite. At Cartersville, Ga., <14-m. material is treated on Plat-O tables, making a concentrate which, after a final magnetic separation, averages 95% $BaSO_4$ and less than 1% Fe (*A TP 973*). Feed comes from two Fahrenwald 6-spigot classifiers; each of the first 3 spigots of the first feeds a roughing table while the other 3 spigots combine to feed a slime table; the first 2 spigots of the second classifier feed 2 roughing tables and the other 4 a slime table. Output of the 7 tables is 25 to 45 tons of concentrate per 10 hr., depending on richness of feed, which ranges from 40 to 70% $BaSO_4$. All middlings are circulated without further classification. Tailing usually carries less than 7% $BaSO_4$, mainly in the form of included grains. The first spigot product of each classifier is treated on a triplex table, all other tables are simplex; all with rubber deck and wooden riffles. Stroke of the triplex table, 1 1/8 in.; others shorter; all speeds, 280 r.p.m.

22. OPERATION OF SHAKING TABLES

Applicability. A separation can be made on shaking tables between any two minerals or substances that differ in specific gravity to an appreciable extent, but unless the concentration criterion is greater than 1.25, separation by reason of specific gravity alone is relatively crude and imperfect; 2.5 or more is sufficient for rapid treatment and substantially complete recovery. When there is a decided difference in shape of particles as, for instance, exists in the case of coal and slate, the heavier particles in this case being tabular while the light are rounded, separation is aided thereby and can be successfully performed even down to a concentration criterion of substantially 1.0. Thus with fine beach gravel consisting of quartz pebbles and oyster-shell fragments, a table discharges the shell over the tailing side while the quartz goes to the concentrate end. Particles of the same specific gravity but of different sizes, all very fine, can be separated to a certain extent, thus removing accidental grit from finely ground abrasives or washing small quantities of slime from granular products.

Table 81 after Fahrenwald and Meckel (*RI 2949*) reports laboratory tests in concentrating variously prepared artificial two-mineral mixtures on a 12×30-in. Wilfley table. Tests 2 to 6 incl. show that when size alone is depended upon for separation, the smaller the proportion of the smaller size present the better. Tests 7 to 11 incl. indicate that separation by size of rounded materials improves as the spread in size between "concentrate" and tailing decreases. This is not in accord with usual experience, and the indication should be checked before action thereon. Test 12 indicates that shape is an appreciable factor and that in a mixture of round and angular grains of the same material, the angular rise to the surface of a shaken bed; this is analogous to the shell-gravel separation above cited. Test 15, taken with 12, shows the advantage, when separating at the same sp. gr., in having the concentrate mineral somewhat smaller as well as more equiaxed than the tailing. Tests 16 and 17, taken with 13, are in accord with general experience that in ordinary gravity separations on a table it is advantageous to have the heavy mineral smaller than the light; the difference in indicated efficiency between tests 16 and 18, in the latter of which the concentrate mineral was the larger, is less than would be expected by experienced table operators. A part of the difficulty is not improbably due to the method of calculating efficiency for the present tests. Tests 19 and 20 are cumulative. Test 21 taken with test 16 simply adds further confusion to a controversy that has continued intermittently for years, *viz.*, whether classified or sized feed is better for tabling. See p. 86.

Size of feed. It is essential that particles settle into the bed in order to be collected as concentrate, hence the lower size limit is determined by the velocity of the cross water and by the movement of the table. The necessary water velocity depends on the size of the particles that are to be washed out. No established mathematical relationship exists for determination of the smallest size of concentrate particle and largest size of tailing particle that can be treated together. It depends, of course, on the relative specific gravities and shapes of particles, the nature of the table surface, character of feed, and other more or less indefinite factors.

Wiggin determined that chalcopyrite smaller than 0.025-mm. could not be treated economically on shaking tables at ANACONDA. Bland found that in treating tungsten slime, 40% of the concentrate would pass a 0.0125-mm. screen when feeding pulp containing 29% solids at 2.4 tons per 24 hr., while all of this material was lost when a pulp containing 8% solids was treated at 4.8 tons per 24 hr. Beringer (*24 IMM 411*) investigated the effect of shake on the settling rate of cassiterite by fastening to a Buss table 2-oz. phials containing cassiterite grains of various sizes suspended in water and noting the time required for the grains to settle. With the table making 270 @ 3/4-in. s.p.m., 0.045-mm. particles settled in 60 sec., 0.035-mm. in 90 sec., 0.030-mm. in 120 sec., and 0.025-mm. in 150 sec. Corresponding sizes with the tables at rest were 0.025-, 0.020-, 0.015- and 0.010-mm. The average minimum size of grain in Buss-table concentrate was 0.05-mm. Johnson and Heinz (*107 J 558*) report sizing

a Tyler standard mesh.

b In tests 7 and below, all mixtures contained 20% of the "concentrate material."

c Side discharge was caught at 15 points, each fraction analyzed (by sizing, or by other means when components were of same size), and cumulative percentage of each component was plotted against sample point, beginning at the head end. Maximum efficiency of separation was indicated at the point where the two curves showed widest divergence. *At that point*, efficiency E was calculated by the formula: E = (% conc. mineral in conc.) + (% tailing mineral in tailing) − 100.

tests on blende tailing in the JOPLIN DISTRICT, showing 2.7% zinc in the sand between 0.833- and 0.295-mm., 2.2% in that between 0.295- and 0.147-mm., and 9.4% in the material passing a 0.147-mm. screen. Similar results reported by Wright (*TP 41 USBM*) are given in Table 82. As a general rule, it may be stated that the granular or sandy portion of material passing a 200-m. (0.074-mm.) screen is readily settled to a shaking-table deck and moved along by the table motion and that good recoveries can be made on such material if the accompanying gangue is not so coarse as to require excessive wash water or excessive tilt to remove it. Watt (*57 A 371*) states that reciprocating (shaking) slime tables do excellent work saving galena coarser than 300-m. and make good recovery of finer galena. In a test on a feed in which 94% of the lead passed a 200-m. screen, the concentrate assayed 76% lead and represented a recovery of 65%; 89% of the lead in the concentrate would pass 200-m.; 98.5% of the lead in the tailing would pass 300-m. Caetani (*3 MM 60*) concluded from testing work at BUNKER HILL & SULLIVAN that on such material reciprocating tables will do better work than vanners. Luyken (*66 G 156*) presents Fig. 65 relating to concentration of 2.5~0-mm. spathic iron ore on a Hercules riffled table. Products at eight zones (No. 1 at head end) along the discharge side were separately screen-sized and analyzed; the ordinates represent relative quantities of iron in the several fractions. The results are completely consistent with Figs. 46 and 47.

Upper size limit is as indefinite as the lower. On tables that pass concentrate across a smooth cleaning plane it is practically impossible to make clean concentrate and finished tailing when the particles are larger than 2-mm., and difficult when they are larger than 1-mm. Full-riffled roughing tables will treat unsized ore material passing a 3/8-in. aperture and deliver a small band of clean coarse concentrate along the upper riffles, and a considerably impoverished tailing between the forward edge of the slime streak and the corner of the table deck. In the great majority of plants treating base-metal ores, roughing-table feed has passed a 2- or 2.5-mm. screen. (See also Table 84.)

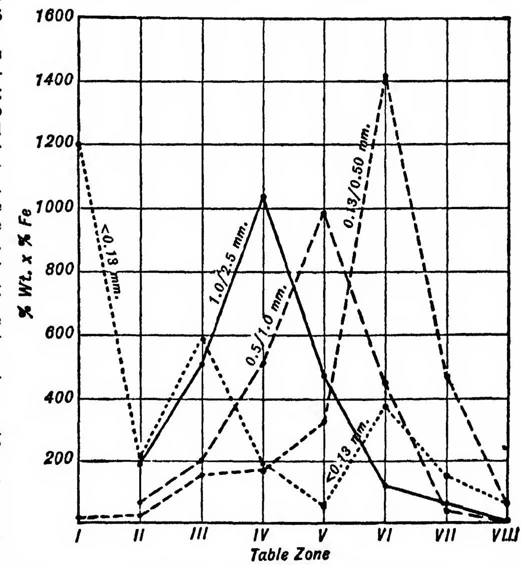

FIG. 65. Distribution of values in shaking-table discharge (feed, unsized spathic iron ore).

Preparation of feed for shaking tables. There has been much discussion on this point. Bibliography of the principal experimental work and discussion is: Richards (*38 A 556*), Bland (*107 J 1112*), Hancock (*24 MM 87*), Cox, Porter, and Gibbon (*14 CMI 490*), Ellis, Table 83 (*7 MMt 156*), Luyken (*26 ME 297; 66 G 155*), and Fahrenwald and Meckel (*RI 2949*). Professor Richards concluded from laboratory tests on artificial mixtures that performances on sized and on classified feeds (both superior to natural) were substantially a setoff, but that with perfect classification the classified feed would be superior. This is the indication of Figs. 46 and 47. Table 83, after Ellis (*7 MMt 156*), presenting results on Coeur d'Alene ore, would justify very little expense for any preparation other than desliming.

The weight of mill opinion is overwhelmingly in favor of classified feed for close work; the contrary opinion is largely based on tests such as those of Richards and of Fahrenwald in which there is no locked middling present. In laboratory testing, usually with much less crowding for capacity than in the mills, and with concentration criteria usually 2 or 2.5 and larger, good separations are readily made; but with middling present and the controlling concentration criteria to be contended with those between pure concentrate mineral and a heavy middling, and between a light middling and tailing, the separation demanded is much more difficult, and the more favorable conditions prevailing with classified feeds must be employed. Furthermore, close fine sizing, as was practiced in the

laboratory tests. cannot be done in the mills as cheaply as classification; cannot, in fact, be done economically at all.

SOUTHEAST MISSOURI lead-mill practice and that of the BOLIVIAN tin mills are representative of modern procedure when gravity concentration comprises all or a large part of the recovery scheme. Table 84 summarizes operating data at a number of Missouri lead mills. Sec. 2, Fig. 100, gives data on feed sizes and preparation. Sec. 2, Figs. 151 to 154, should be consulted for table operation in Bolivia.

Subsequent to the preceding discussion, elaborate test work at MIAMI and INSPIRATION in 1912 and 1913 showed that careful treatment of natural feed on roughing tables with subsequent enrichment of the rough concentrate after classification yielded better metallurgical results, and would certainly yield better economic results, than most careful and elaborate preparation of the whole feed by classification prior to tabling. With ores adapted to concentration by flotation, there can be no doubt that classification of the original table feed is wholly unnecessary from a metallurgical standpoint and is uneconomic; limiting the upper size of roughing-table feed by means of a screen or a mechanical classifier is all that is necessary.

a Part time.
b Making all necessary adjustments except speed, which is fixed for all tables.
i Installed.

Shortly after the adoption of flotation, the swing of practice eliminated gravity concentration from the mills almost entirely. Subsequent experience proved this wise for ores in which readily flotable minerals were finely disseminated. But at mills treating coarsely disseminated ores with large concentration criteria, scalping out concentrate by gravity concentration is now preferred practice. In this work, since tailing is to be re-treated in any event, natural feeds are treated, often with preliminary desliming to prevent dilution of flotation feed. Yet more recently, development of sink-float operation with heavy suspensions to scalp off tailing at coarse sizes has been adopted at a number of plants treating ores favorable to such concentration (see Art. 30).

Capacity of full-riffled tables in ROUGHING service is 100 to 200 tons per 24 hr. on feed through 2- or 2.5-mm. screens. It may be pushed to 300 tons with a feed as coarse as 4-mm. maximum, but at considerable sacrifice of recovery. CLEANING rough concentrate

from full-riffled tables, practically any of the usual sand tables will treat from 40 to 75 tons per 24 hr. When feed is coarse, riffles extended to the concentrate-discharge end will aid in keeping up capacity. Treating CLASSIFIED OR DESLIMED FEED and making both clean concentrate and tailing, capacities range from about 10 tons per 24 hr. on 0.5-mm. material to 40 to 45 tons on 1.5- to 2-mm. feed. In general, the CAPACITY ON LEAD ORES will be higher than on copper or zinc. These same tonnages will apply to recovery of auriferous pyrite from quartz sands, but this is essentially roughing service, as retreatment of tailing by cyanidation is always contemplated and frequently the concentrate is also cyanided.

Table 85. Effect of size of feed on capacity, recovery and grade of concentrate, Joplin ore

Table number	Size of feed			Assays, % Zn			Recovery, %	Operating data

10	0.29	0.70	26.29	5.55	50.82	1.90	68.3	276	3/4

Note. In all cases but No. 9 the tailing was noticeably coarser than the feed. In 1, 5, 8, 9, and 10, more than 30% of the total zinc loss was in <200-m. material. Feeds were successive spigot products and final overflow of a series of 9 hydraulic spitzkasten. Tonnage per table ranged from about 20 per 24 hr. on table 1 to 2 tons per 24 hr. on No. 10.

SLIME TABLES in finishing service treat from 3 to 6 tons each per 24 hr.; roughing auriferous pyrite from quartz, the capacity rises to from 10 to 15 tons, and treating flotation tailing (also essentially roughing service) from 30 to 60 tons per 24 hr. per deck is handled in some mills. Results of tests on Joplin ZINC ORES (*57 A 456*) are shown in Table 85.

Speed and stroke are properly related, a low speed and long stroke being suitable for coarse feeds and the reverse for fine, but in the examples cited in the preceding pages, which comprise a fairly representative cross-section from practice, this relation is decidedly obscure. On the other hand Wright (*TP 41 USBM*) gives results shown in Table 86 to illustrate the effect of wrong *vs.* right stroke length and speed. The average in roughing service is: Garfield, 256 @ 1-in. s.p.m.; Butchart, 261 @ 7/8-in. In sand-finishing service; Butchart, 274 @ 7/8-in.; Wilfley, sands coarser than 1-mm. maximum, 255 @ 7/8-in.; sands finer than 1-mm. maximum, 249 @ 3/4-in.: in slime service, 273 @ 1/2-in. Wright gives practice in Joplin district as follows: Coarse feed (1.5- to 2-mm. limiting), 220 to 240 @ 3/4-in. to 7/8-in. strokes; medium sands, 240 to 260 @ 5/8- to 3/4-in.; fines, 250 to 280 @ 1/2- to 5/8-in.; ungraded feed through 1.5- or 2-mm. screen, 230 to 250 @ 3/4- to 7/8-in., depending on rate of feed. He states that if stroke length or speed is too low, galena packs in the riffles at the head-motion end of the tables and gradually works down into the tailing. Study of details in the various examples of operation, however, shows that variations from the averages are in all cases so great as to throw individuals of any one class into another class. The stroke for slime tables must be much sharper than for sand on account of the greater relative tendency for fine particles, once in contact with the deck surface, to stick. Stroke should, therefore, be correspondingly short in order to prevent agitation of the mass of pulp on the table, whereby settlement is prevented.

Table 86. Tests on effect of speed and stroke length on zinc ores

Test No.	Rev. per min.	Stroke, in.	Feed, % Zn	Tailing, % Zn
1	220	3/4	9.25	0.9
	175	1 1/4	9.25	3.05
2	244	7/8	7.75	1.25
	224	1/2	7.75	3.20

Water consumption in roughing service ranges from about 50 to 350 g.p.t. treated; in finishing service on sands it is usually between 300 and 400 g.p.t., on slimes from 600 to 3,000. Water and transverse slope are interdependent and both are dependent on the size of feed. The requirements are that solids shall settle in the riffles, that the pulp be sufficiently fluid to allow stratification, and that there be sufficient velocity of cross flow to

carry off the upper strata as the riffle support is withdrawn. Granular pulps containing 25% solids and slime pulps containing as high as 30% are sufficiently fluid to allow stratification and are sufficiently lively in the riffles, hence feed pulps may be of these consistencies. Wash water must be supplied in sufficient quantity to form a freely moving film on the deck deep enough to cover the largest particles. Beyond this point transport of material may be gained either by increasing volume at the same slope or increasing velocity by increasing slope. To increase transporting power by increasing slope is economical of water, but it narrows the bands of the various products at the concentrate end and makes accurate splitting difficult. This is allowable in roughing practice, which employs steep slope and minimum water, but when clean products are desired, as in finishing practice, more water is used. Water consumption in slime treatment is exceptionally high on account of the fact that the tonnage of slime per table is low, a certain minimum amount of water is necessary to keep a uniformly moving film flowing, and finally fine particles adhere tenaciously to smooth deck surfaces and require prolonged washing to remove them.

Power consumed averages close to 0.6 hp. per single-deck table and that installed between 0.75 and 1 hp., except that the Garfield table under heavy loads consumes close to 1 hp. Double-deck tables require from 50 to 75% more power than single-deck.

Attendance averages about 30 tables per man in finishing service and 50 in roughing service but as many as 135 tables per man in finishing service are reported from one mill (CALUMET & HECLA) and 106 at another. The number of tables that one man can run depends, of course, on the difficulty of the job. The most difficult service is making finished tailing and concentrate on sand tables with fluctuating feed. The operator in such service must continually change transverse tilt, wash water, and (if possible) the position of the product splitters. In roughing service with full-riffled tables the tilt may be fixed, if the feed supply is steady, wash water is rarely changed, and control is effected almost entirely by shifting the product splitters. In this case one man can attend almost any number of tables, the practical limit being the number that he can keep properly lubricated and running.

Lost time practically never exceeds 1% of possible running time. The principal cause is renewal of riffling and deck covering. In heavy roughing service softwood riffle cleats may last only 1 or 2 weeks and linoleum the same number of months but lost time is cut down by use of hardwood or metal-protected riffles and rubber or concrete decks or metal plates inserted near the feed box, at the point of greatest wear. In ordinary service softwood riffle cleats will last from 6 months to a year or upward and a linoleum deck for 2 to 4 years. If head motions are of proper size and protected from grit they will last almost indefinitely with occasional re-babbiting of bearings and replacement of renewable wearing parts.

Riffling. The principles underlying correct riffling are as follows: Riffles must be deep enough at the head end to bed and protect all material in the feed that can settle out of suspension in the cross flow of feed water, in order to give opportunity for stratification. They must decrease gradually in depth toward the concentrate-discharge end to permit gradual shearing off of the impoverished upper layers by the cross flow of wash water. If the surface is unriffled at the concentrate end, the termination of the riffles should lie along a diagonal line extending from a point near the corner formed by the tailing side and concentrate end to a point on the feed side one-fourth to one-half the distance toward the concentrate end. Such diagonal termination of the riffles results in catching and moving toward the concentrate end such particles of concentrate as are unable to withstand the full flow of wash water on the unriffled surface. If the feed to such a table contains coarse grains of free mineral that tend to go into the middling, extension of occasional thin riffle cleats to the concentrate end, particularly near the feed side of the deck, will result in removal of these particles without holding back much fine gangue. Wright (*100 J 642*) recommends termination of riffles along a curve convex to the concentrate side instead of along the usual straight diagonal, in order to hold concentrate higher on the deck and to spread the concentrate band wider and thus make the cut between concentrate and middling sharper. Garber (*111 J 788*) recommends carrying broken extensions of the regular riffling to a second advanced diagonal for the treatment of complex ores. If the lower end of the diagonal is brought to the concentrate end 2 to 4 in. above the lower corner, the concentrate-middling split can be made on the end of the table where the waggle of the discharging stream is parallel to the cutting edge, with corresponding increase in sharpness of cut as compared with corner cutting. If the middling streak is narrow the middling-tailing cut can also be made on this end. Such riffling, however, requires that the transverse tilt be less, and more wash water must therefore be used. If the concentrate end is cut back diagonally to the feed side, say 6 in. in the width of the deck, the same end is served without the necessity of flattening the table when running and, in addition, the concentrate end is kept wet by wash water supplied at the feed side. When high tonnages

or coarse feeds are treated, shallow riffles should be extended from the separating diagonal to the concentrate end for the full width of the deck in order to hold up concentrate with the steep slope necessary to carry off the tailing. This will result in somewhat lower-grade concentrate than otherwise, but increases recovery. The WIDTH OF RIFFLES is determined in part by the size of the largest grains of feed and in part by the demand as to grade of tailing, other conditions remaining the same. Width must be sufficient to prevent jamming of coarse particles and clogging of riffles; this means that it should be more than three times the diameter of the largest grain. Washing by swirl is greatest in narrow deep riffles, hence these make clean concentrate, but at the expense of higher tailing loss. Steep-sided riffles produce more washing than those with slanting sides. Hence riffles for slimes should be shallow, relatively widely spaced, and have slanting sides. Richards calls attention to the fact that riffle cleats fastened onto a plane surface cause the plane of the roughing surface and that of the cleaning surface to intersect at an angle along the diagonal of riffle termination, thus forming a valley in which the grains pile up and hinder separation. He recommends grooving the riffles into a plane surface to overcome this effect, and this has been done in some tables (Card) and its equivalent has been effected in the plateau arrangement of the Plat-O table.

Cost of tabling ranges from 1¢ to about 6¢ per ton tabled according to the tonnage treated and the consequent opportunity to spread labor cost. Water is the only other real item of expense, since power is very small and maintenance substantially negligible in most cases.

Pneumatic tables. See Art. 36.

VANNERS

General description. A vanner is a concentrating machine adapted to the treatment of fine sands. In its most usual form it consists essentially of an endless belt traveling over head and tail pulleys, and having its upper surface horizontal transversely but inclined longitudinally; the belt and all of its supports are carried on a frame which oscillates in the plane of the belt. The belt is usually made of rubber and the upper surface travels slowly uphill. Feed is introduced about one-quarter of the distance from upper to lower pulley, heavy mineral is discharged as concentrate over the upper pulley and light mineral is washed over the lower pulley.

Types of vanners. Four types are distinguished by the direction and character of shake and direction of slope, *viz.:* (*a*) oscillating side-shake, end-slope; (*b*) oscillating end-shake, end-slope; (*c*) differential end-shake, side-slope; (*d*) gyrating, end-slope. The first are the oldest and were most used, the Frue, Johnston, and Isbell being typical; the Embrey, Craven and Triumph are of the second class; the Luhrig, Weir-Meredith, and Monell are of the third class, and the Senn the fourth. Representatives of only the first and fourth types are discussed herein, as practically the last survivors of the vanner group in present-day mills.

23. PRINCIPLES OF VANNER CONCENTRATION

The vanner is a shaken-bed concentrator in which the bed is of relatively great horizontal extent and small thickness and serves for roughing only; cleaning is done by film sizing (Art. 32).

The slope of the vanner belt is such, when taken with the volume of pulp fed, that a wide shallow stream is formed through which most of the granular part of the feed can and does settle to the belt surface before reaching the tail roller. The up-slope drag of the belt is so regulated as to make the horizontal motion of the material in contact with it, referred to the earth, a very slow travel in the upstream direction. Hence a bed of settled material builds up on the belt. This bed must be kept thereafter sufficiently dilated by the shake to permit reverse classification (p. 03) and gravity stratification. When so maintained it has sufficient fluidity as a whole to permit its top layer to flow slowly downstream while its bottom layer flows upstream. Reverse classification brings the coarse material to the top and this, by reason of the nature of the preparation of vanner feed (Art. 25), is gangue. The bottom layer, which is a rough concentrate, is dragged up-slope past the feed point, and is then subjected to film sizing, which washes out the finer gangue. This latter flows down, joins with new feed, and is, in part, again taken into the bottom layer and returned to the film-sizing zone. But as the bed ages, the layer of fine gangue gradually builds up into the down-flowing upper stratum of the bed, and a balance is reached with the amount of such material leaving over the tail roller statistically equal to that introduced with the feed.

It is not impossible that some adhesion likewise occurs between sulphide or other minerals for which soaps are collecting agents (Sec. 12, Art. 4) and the belt. The rubber of

the belt is a hydrocarbon, the sulphides may be expected to be more or less coated with hydrocarbon-like surfaces from lubricating oils introduced into the ore during mining and crushing (see Sec. 12, Art. 31), and adhesion of hydrocarbon surfaces to each other in the presence of water is well established. The miscellaneous skin-flotation always in evidence around vanner plants treating sulphide minerals lends color to this hypothesis.

24. SIDE-SHAKE VANNERS

Vanners of this group are substantially alike as to method of imparting the side shake, supporting the belt, and causing it to travel; the only important difference, as noted below, is in the character of the crosswise motion, as affected by the manner of supporting the shaking frame.

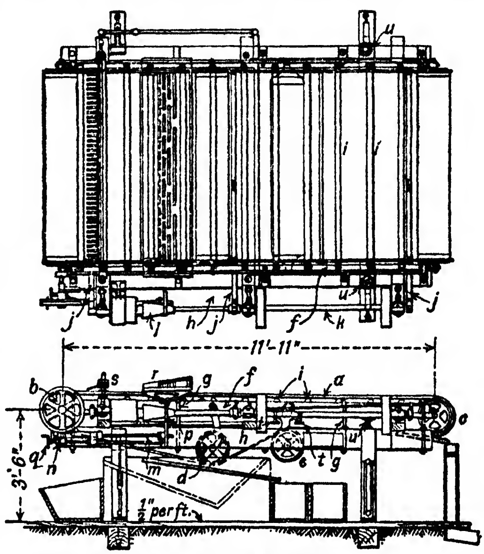

FIG. 66. Frue vanner.

Frue vanner (Fig. 66) has an endless rubber belt *a*, usually 6 ft. wide, with its edges flanged upward, mounted to pass around four large rollers or pulleys *b*, *c*, *d*, and *e*, known respectively as head roller, tail roller, dipping roller, and tightening roller, all carried on a shaking framework *f* which is in turn supported from below on a plurality of lathlike steel springs *g* suitably seated on the framework *f* and main frame *h*. At the central position of the shaking frame, the supports on opposite sides lean slightly toward each other, whence, at the end of a stroke in one direction, that side of the belt rises while the opposite side is depressed, and *vice versa* on the return stroke. Intermediate small-diameter rollers *i* (best made of brass) prevent the upper run of the belt from sagging. The plane of the upper surface of the tail and intermediate rollers below the feed box cuts the head roller about 0.5 in. below the top, thus making the slope of the belt between the feed box and head roller steeper than below the feed box. The intermediate rollers above the feed box conform to the steeper slope. The framework *f* is shaken by means of three straps *j* actuated by simple eccentrics synchronously mounted on shaft *k*, which is carried on the main frame. A cone pulley *l* on this same shaft drives a shifting pulley on the flexibly mounted shaft *m*, on the forward end of which is a worm *n* engaging a worm wheel that is flexibly connected by means of a spiral spring with the shaft of the head roller, thus effecting up-slope travel of the upper run of the main belt. The rate of travel is changed by moving belt *p* by means of hand wheel *q*. The feed box *r* with a suitable pulp-distributing sole is carried on standards attached to the shaking framework *f*. Wash water is applied from box *s*, and a suitable spray for removal of concentrate is mounted under the head roller. Tailing is discharged over the tail roller. The belt is caused to travel straight on the head and tail rollers by swinging the tightening roller forward on the side toward which the belt is desired to travel, by means of hand wheels *t*. Adjusting bolts on the tail-roller boxes may also be used to guide the belt. Longitudinal tilt is adjusted by means of bolts *u*, but the machine must be stopped to make this adjustment accurately.

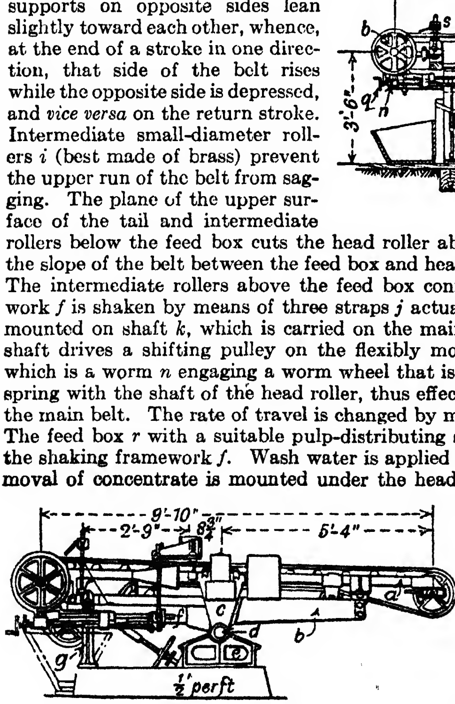

FIG. 67. Isbell vanner.

Isbell vanner (Fig. 67). The shaking frame *a* is supported, at four points, on the ends of two longitudinal leaf springs *b*, set edgewise and balanced on the crossbar *d*, thus facilitating adjustment of longitudinal slope. Side shake is imparted by a single eccentric. Owing to the method of support, the

crosswise motion of the belt is exclusively horizontal and rectilinear. The JOHNSTON vanner is like the Frue, with the important exception that the shaking frame is suspended from four overhanging pedestals instead of supported from below. The suspending links on opposite sides converge downward, whence an edge of the belt rises toward the end of its forward stroke, the reverse of the Frue motion. Of the three side-shake vanners, the Johnston is most free from objectionable sand banks at edges of the belt, probably owing to this characteristic sidewise motion.

Performance and operating data on a few typical examples of side-shake vanners are given in Table 87.

In the ARGONAUT 60-stamp amalgamation mill in 1929 (*IC 6476*) 36 Frue and Johnston vanners treated the plate tailings at average rate of 6.75 t.p.d., extracting sulphide concentrate amounting to 2.42% by weight of their feed. Discharge from each two plates (10 stamps) was classified through a 2-spigot spitzlutte and an 8-ft. Callow cone, each of the three products, sized as in Table 88, being split to two vanners. All vanners operated at 180 s.p.m., with belt travel about 4 ft. per min. Driving power, 3.33 kw-hr. per ton of feed. Labor, 1 man per shift on operation and 1 man per day on maintenance. Assays: feed, $2.25; concentrate, $64.89; tailing, $0.68. In this ore, sulphides carry about 20% of the total value. Frue vanner remains standard in the tin mills of CORNWALL. At the GEEVOR mill (*57 MM 265*) 26 Frues are fed direct from stamps; both products of the vanners receive extensive further treatments, the concentrate by flotation (for eliminating sulphides) and the tailing by three additional Frue vanners, three varieties of sand and slime tables, and round buddles. At the LEEUWPOORT (Transvaal) tin mill (*27 CEMR 308*) nine Isbell vanners are fed in parallel from the last two spigots and overflow of an 8-spigot classifier, together with thickened slimes from a primary washer. The thickened tailings from the vanners pass to three Senn vanners, tailings from which are scavenged on another Senn. Four additional vanners treat slimes from a grinding-classifier circuit reworking sand-table concentrates after removal of pyrite by flotation.

Senn vanner (Fig. 68) is of the end-slope variety, but the shaking frame *a* oscillates both endwise and sidewise on ball-bearing supports *b*. Sidewise shaking motion is trans

mitted from drive shaft c through eccentric d; end shake is effected through eccentric e, cranks f and g, and rod h. Belt motion is transmitted from the drive shaft through friction cones i and worm j to gear k on the head roller. Gyratory movement is depended upon to cause rapid stratification in a thick pulp and allow higher capacities than are usual with vanners.

The Senn was one of the more widely used vanners in the southwestern copper mines. At MORENCI, it is reported to have treated daily as much as 111 tons of ore, in this case up to 2.362-mm. size with 40% of <0.074-mm. Of a slightly finer ore, also at MORENCI, a Senn is reported to have treated 54 t.p.d. Table 87 contains an additional example of Senn-vanner operation.

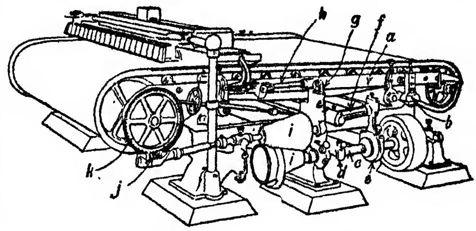

FIG. 68. Senn vanner.

25. OPERATION OF VANNERS

Removal of concentrate from the belt is normally effected by a spray directed at the face of the belt about halfway between the head and dipping rollers. Water consumption here is upward of half of the total for the vanner.

Various mechanical devices (rollers, brushes, etc.) have been employed to remove concentrate either at a higher and more convenient level, or more thoroughly; in the latter case, recovery is often improved by avoiding the accumulation of an adhesive slimy film on the belt. Usual mill practice is to scrape concentrate out of its collecting box with hoes; mechanical and continuously discharging devices have also been installed for this purpose, avoiding occasional damage to the belt.

Size of feed. The maximum rarely exceeds 1.5-mm., the average maximum is between 0.6- and 0.8-mm. The vanner should never be fed with material coarse enough to be treated on shaking tables, since the latter will treat sands with an efficiency equal to that of vanners and at much greater capacity.

Size of grains affects vanner adjustments. Usual practice is to treat fine feed with flat slope, slow belt travel, and little wash water, and coarse feed *vice versa*.

Pulp consistency is usually between 80 and 90% water except on the gyrating vanner where it ranges from 60 to 80%. The pulp consistency should be such that the bed stratifies readily. If the feed is too thick, the bed FELTS, i.e., compacts into a semisolid mass, if there is much clayey slime present, after which excessive wash water must be used to keep sand out of the concentrate, and practically no fine mineral can get through to the belt surface. The only remedy is to loosen the bed with a broom or scraper, sacrificing most of the mineral contained, and start afresh with thinner feed, slower belt travel, or steeper slope. Felting is most common on side-shake vanners, less so with Johnston than with Frue and Isbell; it is less frequent on gyrating vanners, which can therefore be run with very thick feed on account of the greater fluidity of the bed.

Mineral of high specific gravity can be saved with steep slope, slow travel, and much water as compared with mineral of low specific gravity; gangue of high specific gravity will require steeper slope, slower travel, and more water than gangue of low specific gravity. If the ratio of concentration is low, concentrate will come over in a thick sheet with entangled gangue unless the machine is run with steep slope, rapid belt travel, and much water. An ore with a high ratio of concentration, on the other hand, needs slow, careful treatment to save the small amount of mineral and discard the large amount of gangue; hence the machine is run at low slope and slow belt travel with little water.

Capacity varies with size of feed and character of ore, as well as with character of service, *i.e.*, roughing or finishing.

Five to six tons per 24 hr. is close to the average on fine sands containing slimes. A general rule on such material is 1 ton per 24 hr. per ft. of belt width. Caetani (*3 MM 48*) recommended 0.6 ton per 24 hr. per ft. as maximum. In roughing service, making finished tailing only, the capacity is 10 to 20 tons. The Senn vanner at MORENCI treated as high as 150 tons per 24 hr. of feed through 3-mm. Chilean-mill screens in roughing service but shaking tables would be a better installation for such work in general.

The indications of the data cited below are that feed should be finer than tables can handle (Art. 22), that it should be deslimed, and that, if table-size material is fed, the size range should not exceed 10 to 1 for an ore with a concentration criterion of 2.5. The data confirm experience with all bed-type concentrators, *viz.*, that they not only will not save

slimes, but that the presence of slimes decreases their efficiency in treatment of sands. The Richards data indicate that, in the cleaning plane, the water current necessary to wash out coarse gangue also scours out fine heavy-mineral sand.

Richards' (*TB 363*) examination of the tailing of a well run vanner treating <0.75-mm. quartz-pyrite ore showed the average ratio of size of quartz to that of pyrite to be about 10 to 1. In CALIFORNIA GOLD mills 40-m. fine-stamp product was sent to vanners after amalgamation on plates; in CORNISH TIN practice vanner feed comes directly from fine stamps or is the tailing of tables taking feed direct from stamps. Practice at the BUNKER HILL & SULLIVAN West mill, from 1924 to 1929 (*IC 6314*), was to deslime vanner feed in 8-ft. cones equipped with hydraulic sorting pockets like those of the Fahrenwald sizer (Sec. 8, Art. 11). Feed to cones was 92% <150-m.; their spigot product, amounting to 86% by weight, carried 85% of the lead in their feed. Previously, vanners had been fed with unclassified slimes of the same character as the feed to cones, merely thickened to 7 parts water to 1 part solids. Performances by single vanner under the two conditions are compared in Table 89.

Table 89. Performance of Frue vanner on natural and deslimed feeds

	Natural feed			Deslimed feed

Tailing........	2.33	3.3	45	21.34	0.7	9.5

a Equivalent, for comparison with natural feed, to 77% recovery.

Shake is dependent on both length and frequency of stroke. Side-shake vanners are usually run at between 180 to 200 @ 1-in. s.p.m., except that the Johnston is run more slowly (120 to 140) with a stroke between 1 and 2 in. Gyrating vanners run at 140 to 160 @ $^1/_2$-in. to $^3/_4$-in. strokes.

The amount of shake has an important bearing on the minimum size of grain that will settle on a belt.

Slope is closely dependent upon speed of belt, steep slope corresponding to high belt speed and *vice versa.* With side-shake vanners, slope ranges from 0.15 to 1 i.p.f. and is usually steeper with coarse feed or where clean concentrate is desired than with slime feed or in roughing service. Richards' average for all service is from 0.28 to 0.31 i.p.f.

Belt speed determines bed thickness and the thickness of the mixed layer pulled out onto the cleaning plane. Belt speed and wash water are the two adjustments most depended upon by vanner operators for controlling results. High belt speed tends to keep fine mineral out of the tailing but drags coarse gangue into the concentrate unless considerable wash water is used, and this increase in water flowing down the belt may defeat the purpose of high belt speed by keeping fine mineral in suspension. The average speed for side-shake vanners is between 36 and 48 in. per min., with higher speed when a rough concentrate is sought and lower when particularly clean concentrate is desired. Corrugated belts may be run at lower speeds than smooth on account of the fact that fine mineral settles in the corrugations and is protected from the wash water; they must be run slowly when coarse sand is present on account of the difficulty of washing this down-slope.

Wash-water consumption per machine is low, ranging from about 1 to 5 g.p.m., including both dressing water (added on top of belt) and that utilized to remove concentrate from the belt. The maximum water consumption per ton corresponds to attempts to make high-grade concentrate from finely ground low-grade feed. Wash-water consumption per ton of ore treated is less on vanners than on shaking tables in the same service. The SENN vanner uses much less water per ton of feed than other types on account of its large capacity.

Depth of bed is a resultant of all adjustments. Flat slope, high belt speed, coarse feed, thick pulp, and small amount of wash water all tend to produce a thick bed and *vice versa.* Richards recommends $^1/_4$ in. maximum thickness. Beds up to $^3/_4$ in. thick are used when crowding vanners in roughing service but are too thick for finishing. Channeling of bed, either by reason of side banks or center banks, will cause dirty concentrate or rich tailing or both.

Side banks. Frue and Isbell vanners are peculiarly liable to formation of hard banks of sand along the flanges. These creep up into the concentrate and also increase tailing loss. They are formed by any knock or irregularity in the shaking motion such as by a loose or worn eccentric or connecting rod or end play in small supporting rollers or in end rollers. A bank on one side may be formed because the belt is not level transversely. Parallel longitudinal ridges will form if the bed is too thick. The REMEDIES are to increase water, decrease belt travel, or increase slope. The Johnston vanner, on account of the more gentle and tilting side motion, is comparatively free from side banking.

Belt is usually smooth rubber with two plies of canvas and a flanged edge 1 to 1 1/4 in. high. Belts with transverse 60° corrugations spaced 8 to 32 to the inch had considerable vogue in treating relatively coarse feeds. Corrugated belts permit low belt speed but require large quantities of wash water to hold back gangue. This difficulty increases with the size of the corrugations. Tailing is generally lower than on smooth belts but concentrate is correspondingly lower grade. Canvas belt, painted with some water-proof compound, has been used for fine slimes, but it is difficult to wash out fine gangue from the uneven surface without also removing fine mineral. A rubber belt covered with corduroy has been used recently on an Isbell vanner for capturing fine gold in a Colorado mill, and a Frue vanner, similarly equipped with wool blanket cemented to the rubber belt, for fine tin slime in Siam. Belts should be kept sufficiently tight to prevent sagging of the upper surface between the supporting rollers. End rollers are adjustable lengthwise to permit tightening. An eggshell surface, pitted with shallow depressions about 0.6 by 0.1 in., has been made. The life of rubber belts is from 2 to 6 years, if protected from abuse.

Attendance necessary varies with service and regularity of feed and wash-water supply. In finishing service 1 man can attend to 30 to 40 machines, if feed and water supply are regular, but when dirty reclaimed water is used and the wash-water supply consequently clogs, or if the feed is irregular, 1 man will have difficulty with 20 machines. In roughing service a man can handle 100 machines without difficulty. The vanner is a complicated machine, when judged by other concentrators; it requires skilled operatives, and repairs are frequent.

Efficiency of vanners is always low. Recovery rarely exceeds 50%, even on rich galena slimes; it ranges between 20 and 35% in finishing service on copper slimes, and rises to 60 to 75% when making rough copper concentrate.

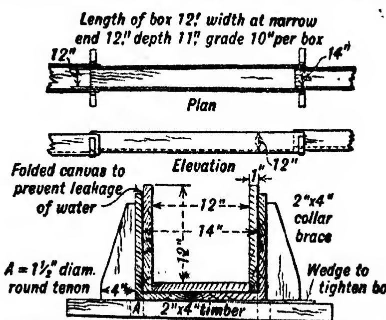
STIRRED BEDS

When a long-range product is stirred at a rate insufficient to maintain the grains in a suspension independent of direct force from the container, reverse classification and gravitational stratification occur. Such beds are stirred beds. The stirring may be effected by tumbling around substantially horizontal axes, as in a tumbling barrel, or as in a sluice; by stirring with a paddle or the like, as in a diamond pan; or by the stirring action of flowing water, as in a gold trap. The beds thus formed act to effect rough concentration. Other means, usually streaming, must be used for cleaning.

26. SLUICE

Sluicing is a form of roughing concentration that is highly efficient in the treatment of low-grade long-range feeds in which the valuable mineral is free, finely divided, and has a concentration criterion of 3.5 or greater. Sluices have been used extensively in washing gold-bearing gravels in all parts of the world; also for working most cassiterite placers; in modified forms they have had considerable use for washing slate and pyrite from coal (concentration criterion, 2); and occasionally have been applied to recovery of metallics from industrial wastes and other artificial deposits (*e.g.*, lead shot from skeet ranges).

Description. Essentially a sluice is an inclined trough or launder (Sec. 18, Art. 16) on a flat slope through which feed is washed (SLUICED) by a rapid stream of water. The bottom of the trough is roughened by strips or blocks (RIFFLES) fastened in place and so arranged as to maintain spaces between them. Arrangements of riffles are legion.



Sides and bottom of boxes are of 1" native spruce, planed on one side. Collars are of rough 2"x4," two per box
Section showing details of collar

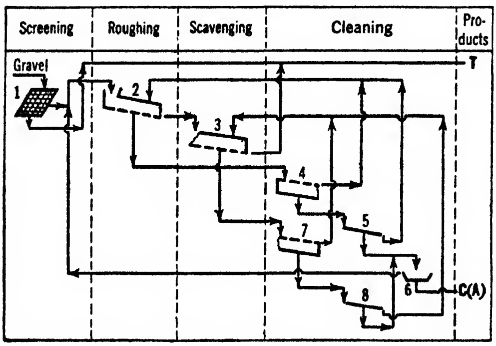
FIG. 69. Sluice box.

The form, size, and elaborateness depend on the scale of work. Sluices for prospecting and small-scale mining work are usually 12 in. wide and deep, made in 12-ft. sections, usually with sufficient flare to allow about 2-in. telescope in joining them together in strings. Some operators prefer butt joints with cover strips, on the ground that they cause less clogging than telescope joints. One-

inch lumber is usually employed for sides and bottoms of small sluices and 2×3-in. or 2×4-in. scantlings for bracing (see Fig. 69). Such boxes will generally serve for a season (4 to 6 mo.), rarely for more than a year of continuous service. Sluices intended for permanent use are made with 1.5- to 3-in. bottom boards and bottom side boards and with 1- to 3-in. upper side boards; usually in 12-ft. lengths, the transverse dimensions depending upon the amount of solid and water to be transported, the slope or grade, and the character of the heavy mineral and gravel.

Action in a sluice. The sluice, like the pan, is a complete concentrating mill.

Flowsheet (Fig. 70). Gravel usually goes first to a screen (1), often overlying a mud box. Thence it is carried by water to the sluice proper. The quantity of water and slope are so regulated that the pebbles and boulders are rolled along the tops of the riffles, but the sand, other than the finest of the light, can settle to the riffle level, and that which fails to settle in the riffles thereafter progresses by a series of leaps under the scouring action of the stream. Essentially the action here, above the riffles (2, 3), is



Legend for Fig. 70.

FIG. 70. Flowsheet of a sluice.

simply further sizing, but it is concentration because the values in the gravel are all in the fine sands. The great bulk of the values settles in the first part of the sluice (2, 4); the balance (3, 7) is for scavenging.

The sand which settles between the riffles is maintained, in a sluice properly built and operated, as a bed stirred by the eddies produced by the roughened bottom over which the water flows, and by vibration of the box under the impact of gravel and boulders tumbling over the riffles. The heavy material settles through the bed to the bottom, and the lighter is gradually displaced back into the stream above until the riffles in (4), in a gold sluice, for example, are filled with a bed of magnetite and associated heavy minerals (black sands) through which gold can sink but into which quartz sands and the like do not penetrate (Art. 1). Action in (7) is similar to that in (4), but it takes longer here to establish the black-sand bed, and it is never as dense as in (4). In the clean-up (items 5 and 8) the bottom of the sluice acts as a smooth strake (Art. 34). Since the clean-up starts from the head end, the middling washed away is again presented to the roughing section (2). Clean-up of the lower section (item 8) is normally made much less frequently than that of the upper.

The concentrate of the clean-up is treated more or less elaborately according to the scale of the operation and the size of the gold. In the simplest case, with reasonably coarse gold, it is simply panned (item 6). If the gold is fine, mercury may be added here, and the concentrate is an amalgam. When the gold is fine, mercury is often added at the head of (2) during the roughing operation to aid in holding gold in the riffles. For details of more elaborate clean-ups, see Sec. 2, Art. 21.

The essential requirement for effective saving of fine heavy values is the loose, active bed of sand in the inter-riffle spaces. This should be maintained in place as a whole, while losing content only from the top layer, continuously adding heavy material to the bottom layers. The rapidly moving mass of coarse gravel above the tops of the riffle cleats should not interfere with access of sand to the riffles, nor yet splash material (settled sands, gold, amalgam, etc.) out of the riffles. The two desiderata are not necessarily inconsistent.

Gravel transport is effected by sliding and rolling along the tops of the riffles, in the case of the largest particles, and a leaping motion (SALTATION) in the case of the finer intermediate sizes. Sand either hugs the bottom, with some saltation above the riffles, or is maintained wholly in suspension; the latter gives poor recovery.

The surface of the water in a sluice is either wavy or smooth. A smooth surface indicates a smooth hard surface of settled sand in the bottom and poor gold saving. The wavy surface reflects ripple ridges on the bottom; these ridges and the resultant waves may move either upstream or down. In the latter case the ridges or dunes are moving by erosion on the upstream slope and deposition on the downstream side of the crest. This accompanies underload and represents a tight bottom, which is bad for gold saving. Up-moving dunes (anti-dunes) represent erosion on the downstream side and deposition on

the upstream side; they connote an eddying or boiling activity of the sand in the lee of the dune, which makes for good gold saving; it is a concomitant of overloading. Hence, paradoxically, an incipiently overloaded sluice is not only a superior tailing-transport device but is also a better gold saver. Excessive overloading requires excessive water to prevent clogging; in this condition fine gold is carried away unless undercurrents are provided.

Sluice boxes should be made thoroughly watertight. The lumber should, therefore, be surfaced and sized, free from knots and cracks, but it need not necessarily be tongued and grooved. Joints are closed by soft-pine splines, batten strips outside, or oakum caulking. Side liners of rough lumber or sheet steel are used in all but the smallest boxes. These side liners may serve as hold-down cleats for the riffles. Sills and posts for large sluices are made of 4 × 6-in. or 6 × 6-in. lumber and spaced about 3 to 4 ft. apart. On every second or third set the posts should be braced to the sill with 1 × 6- or 1 × 8-in. angle braces and the sill should be about twice as long as the sluice width to give proper slope to the braces. The bottom and sides should be spiked to the sills and posts with 30d and 20d spikes respectively, spaced about 4 in. (*Bowie*).

A large sluice used at LA GRANGE mine in California is shown in Fig. 71, item F. The sides, bottom, and side liners are 3-in. plank. Rail riffles, set longitudinally in the head end of the sluice and transversely below, are used.

AUSTRALIAN practice differs (*17 MM 16*). Boxes for gold gravel are made 4 to 8 ft. wide, 12 to 15 in. deep, and 60 to 100 ft. long, in 12-ft. sections, and are bolted together with flush joints and outside cover plates. Boxes for tin gravels are 10 ft. wide, 18 in. deep, and 120 to 200 ft. long.

Riffles are placed in sluices to hold a bed but also, to an important extent, to disintegrate the gravel; thereafter, having satisfied these primary requisites, to aid in transporting gravel. They perform the first function by roughening the bottom surface of the sluice, thus decreasing the velocity of the lower layer of water and permitting sand to settle readily. The interstices furnish protection to the settled material from the horizontal transporting effect of the stream. All riffling is conformed to hold the bed securely and at the same time to promote stirring by the overpassing current (BOILING). Disintegration is effected by causing the boulders to tumble instead of slide.

Pole riffles (Fig. 71, item A) are probably the most common form for small sluices, when a maximum amount of material is to be moved with a minimum amount of water, gold is coarse, and loss of a small

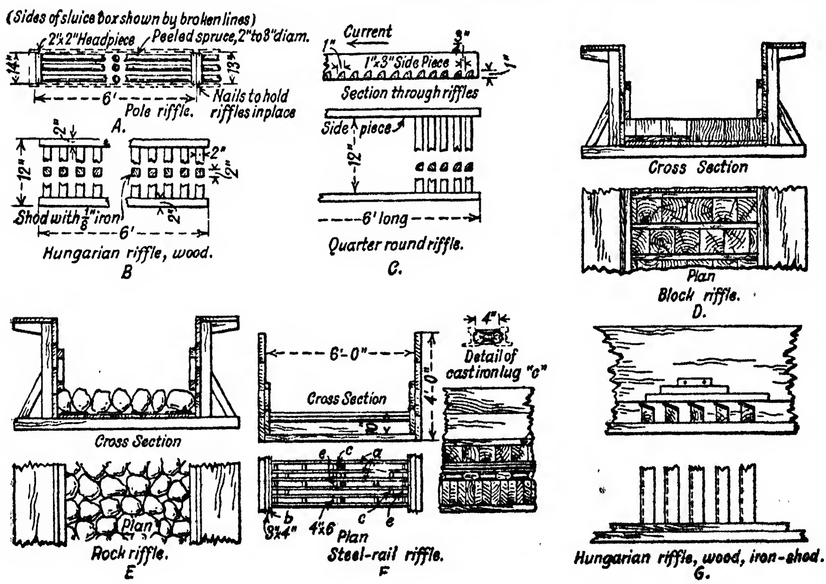

FIG. 71. Riffles.

amount of fine gold is relatively unimportant. They are made normally of 2- to 6-in. peeled poles or 3 × 3-in. squared strips spaced 1 1/2 to 3 in. in the clear and made up in units of convenient length to handle, *e.g.*, 6 ft., by transverse straps nailed on at both ends. Pole riffles wear quickly but are inexpensive. At one plant 1 1/2 sets of 4-in. lodgepole pine riffles wore out in 30 days, after handling 18,000

cyd. At another plant a set lasted 10 days, handling 1,100 cyd. (*IC 6786*), but the usual life is much longer. Squared riffles are often protected by angle iron. The end straps are cut to fit snugly across the sluice box and are normally held in place by nails driven into the ends through the sides of the sluice, but cleats nailed to the sides above the water line, obviating nail holes below water level, are better. A somewhat similar riffle, made of 1 1/2×6-in. plank set on edge longitudinally, spaced by 1 1/2-in. blocks, and shod on the upper edge with an iron bar 1 in. × 1 1/2 in. is described by *Bowie*. Variants of this have been used elsewhere. Hutchins (*Bul. 263 USGS 200*) describes a pole riffle with 2×2×1/16-in. pieces of sheet iron driven into the poles cornerwise, long axis parallel to the poles, for use in disintegrating clayey material.

Rail riffles (Fig. 71, item F) are used in large sluices where resistance to wear is an important factor. They are commonly set lengthwise on transverse sills, in which case their action is similar to that of pole riffles; or they may be set transversely. Longitudinal-rail riffles are made up in 6-ft. lengths and the width of the sluice box. They are usually set bottom side up and held together by tie rods with wood or special metal spacers (Fig. 71, item F). Bouery (*95 J 1055*) found that the life of rails set transversely was greater than with longitudinal setting, that between 4 and 6 in. c-c. was the best spacing for transverse setting, considering duty of both water and gold saving; and that with longitudinal setting wear was more rapid with 8-in. spacing than with 5-in. He also found that when rails were set directly on the bottom of the sluice the gold-saving capacity was insufficient and therefore devised and used the combination riffling shown in Fig. 71, item F, in which the principal function of the rails is to protect the wooden riffles from wear and to increase the transporting duty of the water; 45-lb. rail riffles set longitudinally handled about 32,000,000 cyd. of water and 2,500,000 cyd. of gravel before replacement was necessary; the same weight rails set transversely handled 50% more material, with spacing in both cases 5 in. c-c. Cast-iron bars, *e.g.*, 1 1/2×3-in., are used in the same way as rails. Strap, 1/2×3-in., spaced 1 1/2 in. in comb cuts in 2×4-in. wood cross strips 4 ft. apart are also reported (*IC 6786*).

Block riffles (Fig. 71, item D) are the commonest form in all large sluice lines. The blocks are usually about 8 to 13 in. long, either squared or round, 6 to 20 in. in diameter or on an edge. They are nailed to 1- or 1 1/4×2- or 3-in. cross strips before being put in place, and these strips are nailed through the sides of the sluice. Holding-down strips nailed to the inner sides of the sluice are also used. Squared riffle blocks are usually spaced about 1 in. from face to face transversely (thereby differing from the figure) and the nailing strips produce a spacing of about 1 in. longitudinally. Longitudinal joints are preferably staggered in adjacent transverse rows. Round blocks are fitted as closely together as possible when fastening them to the nailing strip.

Block riffles produce a large amount of drag; they offer good protection to settled material and cause sufficient boiling to remove a considerable amount of sand from the concentrate. Their disintegrating effect is low, but, in compensation, they interfere but little with transport. *Bowie* advises the use of block riffles in the head boxes at all times. Their ADVANTAGES are: cheapness, efficiency in gold saving, ease of removal and clean-up; their DISADVANTAGES are rapid wear and difficulty in setting on account of tendency to float. At LA GRANGE, when handling 1,000 cyd. of gravel per hr. in a 6-ft. sluice, the life of pine blocks was only 17 days (*95 J 1056*), but average life is probably nearer 60 to 70 days. A set 7 in. long lasted two seasons, handling 140,000 cyd. of gravel (16-in. max.) on a flat grade (*IC 6786*). *Bowie* states that nut or pitch pine or a wood that is long-grained and "brooms" readily is best and deprecates the use of oak or other hardwoods that wear smooth. Gardiner and Johnson (*IC 6786*) say that, of the western conifers, the Douglas fir wears best. Round blocks are more difficult to set than squared but may cost sufficiently less to be economical. Welton (*20 IMM 172*) criticizes block riffles on the ground that gold does not readily settle in them and that they absorb gold values. The first criticism is not in line with general experience. There is, undoubtedly, some catching of gold in interstices in the blocks themselves, and old blocks should be and commonly are burned and the ashes panned. Longitudinal rails are sometimes set in blocks to decrease wear and drag.

Rock or stone riffles (Fig. 71, item E) are made by packing the bottom of the sluice with selected rocks 8 to 10 in. diameter, usually flattened, with or without some hand dressing, set on edge, inclined slightly with the run of the material, and with the longer dimension transverse. They are prevented from shifting longitudinally by transverse poles nailed in at intervals of a few feet. No devices for holding down are ordinarily necessary but with large quantities of coarse gravel they may become displaced. Rock riffles wear longer than block riffles and are more effective in breaking up cemented gravel, but they are more expensive to set and to clean up. They also require more water and greater slope to handle a given quantity of a given gravel. Welton says that under conditions requiring 1/2 in. per ft. slope with block riffles, rock riffles will require 3/4 in. per ft. They are commonly used in California for a short distance at the head of the sluice line and also in the tail sluices following block riffles, where their principal function is as a chute liner and clean-ups are infrequent.

Rock for riffles should be hard and uniform in size and hardness. Quartz is probably the best material, if locally available. As between block and stone riffles, Welton states that the former will collect three times as much gold in a given length. He ascribes this to the fact that with the rocks there is no continuous bar formed across the sluice and that the gold, therefore, works along more readily and for longer distances.

Hungarian riffle. This name is used by different writers to denote different forms of cross-stream riffles made of wood, wood iron-shod on top, steel, and cast iron or cast manganese steel. They are generally considered the best form for fine gold. Probably the nearest to a common characteristic in all riffles so named is an overhang on the downstream side. Fig. 71, item G, shows one form so made that the overhanging strap slopes upward slightly on the downstream side. It is frequently claimed for this type of riffle that it is good for disintegrating gravel, but Perrett (*122 P 417*) rightly remarks that a sluice is not an efficient gravel disintegrator and that the use of obstructive riffles to effect disintegration results in undue loss of capacity. Wear is higher than for poles. Angle irons set on cross slats with one leg vertical and the other, pointing downstream, forming the upper surface, spaced 1 to 2 in. from edge of flange to back, are closely akin to this type. Riffles formed by gouging or boring out pockets in plank

(PIT RIFFLES) are also called Hungarian riffles (*Wilson*) as are also transverse square riffles without overhang. (Fig. 71, item B) (*100 J 995*). Pit riffles are used with mercury in the treatment of fine material. They are not suitable for coarse material on account of the fact that mercury and amalgam are splashed out of the depressions by impact of the large stones. Another form of pit riffle, used at intervals along the sluice lines on Yuba dredges, consists of a section of ordinary Hungarian riffles fitted with a bottom to hold in quicksilver and with the inter-riffle spaces divided to form small quicksilver pockets. RUBBER-CAPPED RIFFLES are reported (*26 #3 MCJ 22*) to outwear angle-iron or steel-capped wood; 1/4-in. soft rubber strip is used with 1/4-in. overlap; all-rubber riffles are more costly and heavier.

Miscellaneous riffles. A large number of other riffle forms have been used. Expanded metal over cocoa matting is common on dredge tables.

Moline (*17 MM 16*) describes several riffles used in Australian gold practice. A so-called Venetian riffle is used in certain parts of Russia (*15 MM 148*). The natural surface of bedrock or a bedrock surface crudely riffled by cutting transverse gutters forms the first gold-catching surface in some hydraulic mines. The grade must be much greater (*Wilson* says twice) than that of a wooden sluice for the same material. Hutchins (*105 J 861*) describes the use of a riffle in a Siberian sluice, consisting of perforated plate with 3/4-in. apertures, set 3 in. up from the bottom. Old car wheels laid close, flange side up, have been used (*IC 6787*). Blankets, corduroy, hides with the hair up, canvas, velvet, carpet, cocoa matting, and sod have all been used as gold-catching surfaces (see Art. 34). Alternation in type of riffling is reported to decrease packing (*141 #4 J 39*).

Mercury traps made by cutting depressions in a board, such as transverse grooves, 1 to 1 1/2-in. auger holes, or 2 to 4-in. half-moons, to hold mercury, are used with fine gravels, particularly on dredge tables and in undercurrents. Coarse gravels splash out the mercury.

Comparison of riffles. The bases of comparison are gold saving, cheapness, durability, ease of assembly, installation, and removal. It is impossible to classify riffles in other than most general terms with respect to their ability to perform their various functions. Riffles presenting a uniformly roughened upper surface of relatively fine texture have maximum retarding effect on the lower layer, but do not roughen the water surface, and roughening is desirable for catching fine gold. Transverse riffles forming a complete bar across the bottom of the sluice afford maximum protection to settled material and also cause considerable boiling, which enriches concentrate, but they obstruct the passage of gravel and consequently lower capacity. Longitudinal riffles cause the least drag on the lower layers of the stream and offer the least obstruction to the passage of gravel; they also offer minimum protection to settled material and are more subject to scouring action. The life of different types and the ease of removal and replacement are important considerations. In many cases the availability of a given riffle material or the prejudice of the operator is the deciding factor. Frequently more than one type of riffle is used in the length of the sluice line. Of 80 mines reported in *IC 6786*, 25% used Hungarian, 20% pole, 15% block, 15% rail, 25% miscellaneous, including angle-iron, expanded metal, or screen over fabric, rock paving, and cast-iron bars.

Slope of the sluice line depends on the character of the gravel, character of the gold, kind of riffles, and quantity of water available. Flat and shingly gravel requires more slope than rounded gravel; coarse gravel requires greater slope than fine. Very fine gold may be carried in suspension in the water if the slope is steep and the velocity correspondingly high, especially if there is much clay or mud; on the other hand, moderately fine gold is best caught in "rough" water and this condition is obtained by steep slope. Obstructive and transverse riffles used for disintegrating clayey and cemented gravels require steeper slope than longitudinal or block riffles. Restricted water quantity demands steep slope, if the maximum quantity of gravel is to be handled. With a given amount of water narrow sluices require, of course, less slope than wide. As a general operating rule, the slope should be such that the water used will transport the rocky material and prevent sand from packing in the riffles. Excess increases wear markedly and decreases riffle effectiveness. If water is scarce, however, slopes may be as great as 2 in. per ft., but with serious drop in recovery. Carrying capacity with a given water supply increases more rapidly than slope. Early boxes may be set flatter than regular grade, as may also end boxes, if fall is available. When unusual slope must be provided for boulder transport, an undercurrent should be provided to prevent loss of fine gold.

Bowie states that 6 to 6.5 in. per 12-ft. box is usual; 9 in. to 12 in. when much clay is present. Rounded gravel containing considerable clay or soil may be moved on a slope of about 2 in. per 12 ft. but it is better to have as much as 6.5 in. per 12 ft. to increase capacity and lessen the labor required for handling large boulders. Coarse gravel needs from 6 to 10 in. per 12 ft. and considerably more water than fine gravel. *Van Wagenen's* rule for slope for handling average gravel is: $F = V^2P/2A$, where F = fall in ft. per mile, V = velocity in ft. per sec., P = wetted perimeter in ft., and A = area of stream in sq. ft. *Wilson* gives Chezy's formula for the velocity V, in ft. per sec., necessary to transport boulders of average diameter a in ft. and specific gravity g as $V = 5.67\sqrt{ag}$. Williams (*56 MM 218*) states that in GUIANA grades are 5% for loose sand, 10% for loose sand and gravel, and 12 to 15% for heavy ironstone gravel. For clayey gravel, water is reduced and slope increased to increase puddling in the sluice. Perrett (*122 P 417*) states that the shingly Siberian gravel, when unscreened,

requires a slope of 18 in. per 12-ft. box. Sluices for catching lighter minerals such as cassiterite and sapphire are usually set on flatter slopes, ranging from 4.5 to 6 in. per box.

Newman (*138 J 230*) calls attention to the fact that with sandy gravels and fine gold, increasing slope increases activity in and looseness of the sand bed and tends thereby to increase recovery.

Water-carrying capacity. *Bovie* gives the following data: A sluice 6 ft. wide, 36 in. deep on 4 to 5% grade will run 3,000 to 5,250 cu. ft. of water per min.; 4 ft. wide and 30 in. deep, 1,200 to 2,250 cu. ft. per min. on a 2.1% grade and 3,000 cu. ft. per min. on a 4% grade; 3 ft. wide, 30 in. deep, 900 to 1,500 cu. ft. per min. on 1.5% grade. Assuming the wetted depth to be 50% of the total depth, which is usual, these figures correspond to average water velocities in the sluice of 4 to 10 f.p.s. Table 90 is from Gardner and Johnson (*IC 6786*). *Van Wagenen* states that the moving power of water in sluices varies with the velocity as follows: 16 f.p.m. begins to wear away fine clay, 30 f.p.m. just lifts fine sand, 39 f.p.m. lifts sand grains up to 1/16-in. diameter, 45 f.p.m. moves fine gravel, 120 f.p.m. moves 1-in. pebbles, 200 f.p.m. moves 2- to 3-in. pebbles, 320 f.p.m. moves boulders 3- to 4-in. in size, 400 f.p.m. boulders 6- to 8-in., 600 f.p.m., boulders 12- to 18-in. Rounded pebbles move, of course, more easily than flattened shapes, and pebbles of low sp. gr., *e.g.*, acid rocks, more easily than greenstone or basalt. In all cases the depth of water must be sufficient to cover the largest particle to be moved; but 6 to 8 in. is the normal maximum when large boulders are absent; packing increases with depth. The bottom width should be 1.75 to 2.25 times the wetted depth for maximum water-carrying capacity. Wider sluices clog on account of relatively low velocities.

Table 90. Water-carrying capacity of sluices (*IC 6786*)

Width, in.	Miners in.
12	25– 100
18	100– 300
24	200– 600
36	500–1,300
48–60	1,000–3,000

Length depends principally upon the character of the gold, less upon the dimensions and slope of the sluice and the kind of riffles. Coarse and granular gold settles quickly and is easily held in the riffles, fine and porous gold is carried long distances by the current. With low velocity in the sluice, riffled length must be greater to compensate for smoothness of flow. Long sluices aid disintegration. See also ***Distribution of gold in sluice,*** p. 102.

The minimum length for relatively deep, narrow sluices is 500 to 600 ft.; the sluice line at some mines is several thousand feet long, but this great length is as often for transport of tailing to a suitable dumping ground as for saving fine gold. Maximum length of Alaskan sluices is about 200 ft., limited by flat slopes; coarseness of the gold permits reasonable recoveries. Length may be less in hydraulicking than with shoveling because disintegration is effected ahead of the sluice.

Width is the first factor to be considered in design. Proper width depends on maxima and minima of available water, slope, and the size and quantity of boulders that must be transported. Newman (*loc. cit.*) relates width to water, which in turn is determined by the amount and size of solid to be carried (p. 103). Newman's figures are: for 200 to 300 miner's inches, 24-in. width; for 400 miner's in., 30-in. width; 600, 36-in.; 1,000, 40-in.; 1,500 to 2,000, 48-in.; 3,000, 60-in.; when grades are 5 to 7 in. per 12-ft. box, and average gravel and boulder conditions, corresponding to a duty of 3 cyd. per 24-hr. miner's inch. Williams (56 *MM* 218) recommends a wide sluice in order to insure less velocity change across the box. See also ***Water-carrying capacity.***

Drops up to 12 in. in height in the line of boxes are of use in breaking up cemented and clayey gravel and in causing gold to settle in the riffles. Drops of 3 or 4 in. should be allowed at junctions and branches.

Curves lessen the velocity of the stream and cause deposition of solid matter with resultant clogging of the sluice. They should be made as gradual as possible.

Wilson recommends elevation of the outer edge 1 in. for every degree of curvature and an increase in slope of about 1 in. per box for a short distance (2 or 3 box lengths) below the curve.

Mud box or **dump box** (Fig. 72) is frequently used at the head of a sluice line when material is fed in batches, as by horse scraper, drag line or derrick bucket or the like, and contains much clayey or cementing material, or when water is scarce. In it the material is worked over and disintegrated by means of a coarse-tined rake or fork, and large boulders are removed. It may be riffled or not. If so, rock riffles are usual. The slope is steeper than in the main string, usually about 1 in. per ft. Much coarse gold is caught here, and clean-ups should be frequent. Usual length is 12 to 15 ft. but some are 100 ft. long and worked mechanically. Riffling is pole, block, or rail.

Undercurrent is a device used in connection with sluice lines to catch fine gold from the finer material fed to the sluice. In order to treat the material in a thin film and thus get the turbulent current and small settling distance necessary for catching fine gold, the undercurrent is made wide; it must be made correspondingly steep in order that the water may have sufficient velocity to move the gravel. A perforated screen or a grizzly usually with 3/8-in. to 1-in. openings is set with its upper surface about 1 in. below the top of the riffles in the main sluice. Grizzly bars ordinarily run lengthwise, but transverse setting may

be used when water supply is ample. The area and aperture of the grizzly must be such that the main sluice is not robbed of so much water that it will not carry the coarse tailing. Undersize is led off in a converging launder, with suitable distributing devices to spread the feed evenly across the width of the undercurrent. The latter is proportioned to the size of main sluice and the quantity of gravel carried. Normally it should be located near the end of the main sluice.

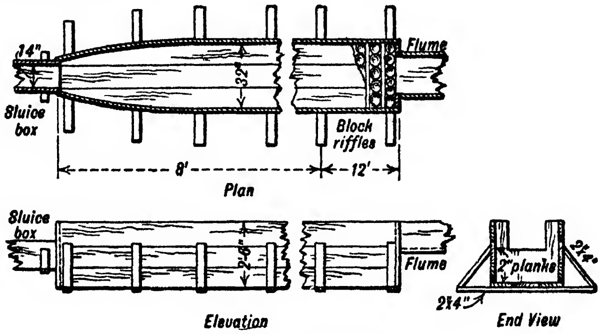

FIG. 72. Mud box.

The WIDTH is usually 5 to 20 times that of main sluice and the length ranges from 10 to 50 ft. Welton (*loc. cit.*) recommends an undercurrent 20 ft. wide and 30 ft. long for a 4- to 5-ft. sluice. He also recommends dividing such an undercurrent by longitudinal walls into four sections, thus allowing three to be run while one is being cleaned up and reblocked. This is a good arrangement, since the undercurrent must usually be cleaned up more frequently than the main sluice. The USUAL SIZE of undercurrent in Alaska for a 12-in. sluice line handling 400 to 500 cyd. per day is 20 ft. square. The SLOPE is usually about twice that of the main sluice; *Bowie* recommends 12 in. per 12-ft. box for longitudinal plank or pole riffles, 14 in. for blocks, and 16 in. for stones. RIFFLES are of the same types as used in the main sluices, except that wear is less severe and gold catching more important. Blankets, burlap, or matting with screen cover are also used; they should be washed every day or so. Mercury is usually used. Riffles are placed also in the distributing launder. TAILING is usually led back into the main sluice. The RETURN SLUICE should enter the main sluice at an acute angle and with little or no drop, in order not to interfere with the flow in the main sluice.

Recovery in undercurrents varies according to the character of the gold and the sluice treatment preceding. Welton says that an undercurrent following 500 ft. of sluice should make 10 to 15% of the total combined recovery, but this is high for usual practice. It frequently runs as low as 2%. When less than 5% recovery is made, it becomes questionable whether the installation pays its way. When mercury is used in the main sluice, undercurrent may be necessary as a guard against amalgam loss.

Tables are short, wide sluices, usually set on a relatively steep slope, taking a finer feed than the ordinary sluice and usually operated with some mercury in the riffles. Their principal use is on gold dredges (see Sec. 2, Art. 21).

Hutchins (*105 J 861*) describes a table installation in Siberia where material through a 1-in. screen was treated on tables 10 ft. wide by 30 ft. long set on a slope of 2.25 in. per ft., the tailing after passing through a 0.5-in. screen passed over a similar set of tables on 2-in.-per-ft. slope, and this tailing after screening through a 1/4-in. screen was sent over a similar set of tables on 1.5-in.-per-ft. slope. There were a few riffles on these tables, but sand packed behind the riffles and spoiled their usefulness. Very little gold was caught, most of it being caught in the sluice preceding the tables. It will be noted that this is an undercurrent installation.

Perrett (*122 P 417*) argues for tables as opposed to the ordinary sluice on the score of compactness, low water consumption, and high gold saving. He cites a Russian plant with tables 38 ft. long on which 97.56% of the total recovery made was made on the first 10 ft., 1.95% on the following 14 ft., and 0.49% on the last 14 ft. The loss was 0.6 grain per cyd.

Water consumption is extremely variable.

Hutchins (*105 J 861*) states that ordinary cemented gravel from CALIFORNIA DRIFT MINES requires from 7 to 13 cu. ft. of water per cu. ft. of gravel and hard cemented gravel requires from 20 to 27 cu. ft. on the average. *Bowie's* figure for NORTH BLOOMFIELD, treating mostly top gravel in 6-ft. sluices with block and rock riffles on a slope of 0.54-in. per ft., is 18 cu. ft. of water per cu. ft. of gravel and at LA GRANGE, in a 4-ft. sluice with block riffles on a slope of 0.25 in. per ft., 56 cu. ft. Purington (*Bul. 263 USGS 142*) gives 40 cu. ft. of water per cu. ft. of gravel with block riffling on 0.33 in. per ft. slope under most favorable conditions in SOUTHEAST ALASKA. In the ATLIN DISTRICT, B. C., with pole riffles on a slope of 0.67 in. per ft., 20 cu. ft. of water per cu. ft. of gravel was used. At the Bowlder Creek mines of SOCIÉTÉ MINIÈRE COLOMBIE BRITANNIQUE a 24-in. sluice on a slope of 0.5 in. per. ft., with block and rail riffles, required 80 cu. ft. of water per cu. ft. of gravel, of which 50% was boulders

18 to 30 in. diam. A KLONDIKE bench-gravel sluice, 24 in. wide on a 1-in.-per-ft. slope, with block riffles, required 20 cu. ft. of water per cu. ft. of gravel. 12-in. sluices in ALASKA in shoveling-in work require 45 to 90 cu. ft. of water per min. Hutchins gives 80 cu. ft. of water per cu. ft. of gravel as an example of inefficient washing of clayey gravel in SIBERIA. Consumption on NEW ZEALAND GOLD DREDGES is given (*16 MM 81*) as 75 cu. ft., while on tin dredges about 20 cu. ft. is provided. Perrett (*122P 417*) says that not over 33 to 40% of the amount of gravel can be washed in a sluice with a given amount of water that can be washed in a plant equipped for removal of oversize, with subsequent treatment on gold tables. (See also Sec. 2, Art. 20.)

Operation (see also Sec. 2, Art. 20) consists in keeping gravel running through the sluice, undercurrent, or table, until the riffles are so filled with concentrate that an excessive amount is going into the tailing, then cleaning up. Prevention of clogging, with maximum duty of water, requires a steady flow of water, adapted to the slope of the sluice and the maximum size of gravel. Any marked departure from this optimum will cause scouring of settled sand, with attendant loss of gold, or excessive sedimentation and plugging of the sluice line, which imposes additional cost for sluice tenders. Rigorous exclusion of oversize material will tend to prevent plugging and will save much wear and tear on the sluice line. On the other hand, packing in riffles may sometimes be remedied by sending more coarse material into the sluice line. The time between clean-ups depends upon the sluice and the character and quantity of gravel treated. The interval should be made as long as possible, especially at operations where the water season is short. Uusually the head sluices are cleaned up at approximately regular intervals of 1 to 4 weeks, as dictated by experience, while the tail sluices are cleaned only once or twice per season and are depended upon to catch any gold that passes the head sluices by reason of too great an interval between clean-ups. Dredge clean-ups are more frequent because of the relatively short sluices and greater danger of tailing loss.

Cleaning up. Practice varies. Commonly the supply of gravel is stopped and clear water run until the tops of the riffles are clear of gravel. The flow of water is reduced. The riffles are then lifted out, beginning with the first box, and washed carefully into the sluice. Any fabric in the sluice is removed at the same time and carefully rinsed into the box, or scrubbed in a tub. Fabric ready for discard is dried and burned and the ash washed. After all the riffles in a given section, say 100 ft., have been removed, a light flow of water, just sufficient to move the material slowly, is turned on and the concentrate is carefully and slowly turned over by means of wooden paddles 3 or 4 in. wide pushed upstream along the bottom. Rocks are thrown out by hand. Welton (*20 IMM 172*) describes a special clean-up shovel made of light sheet steel with flat bottom, sides turned up 1 in. and back sloping at 45° to the bottom. The shoveler faces downstream to pick up a load and turns around and holds the shovel in the stream, when light material is washed over the back, leaving rich concentrate on the shovel. As material works downstream, a head of enriched material is left behind. This is carefully collected and further concentrated in a pan or rocker, with or without mercury, as circumstances dictate, or it may be brushed against a flat stone in the sluice, which serves as a planilla (Art. 34). (When the gold is amalgamated, iron or granite pails, not galvanized or tinned, should be used for collecting concentrate.) The succeeding section is next treated in the same way, or, in some cases, concentrate from the lower sections is carried in pails to the head of the first section and there cleaned. Finally gold is collected from crevices by means of a brush and scraper, or a pointed amalgamated-copper spoon. Considerable gold may get so far into crevices that it cannot be collected in this way. Such gold is recovered, when the sluice is worn out or the working is abandoned, by burning the sluices and panning the ashes. Ellis (*100 J 993*) states that some Alaskan boxes on burning have yielded as much as an ounce of gold.

The time required to clean up and reblock 100 ft. of 4-ft. sluice is about 4 hr. (*20 IMM 208*). When time is an important element, the clean-up may be carried only to the point of washing out light sand, when the heavy sand concentrate with contained gold and amalgam is shoveled out and further concentrated in pan, rocker, or small sluice, or it may be sold or treated with mercury and cyanide in a tumbling barrel.

Distribution of gold in sluice. The bulk of the gold content of gravels settles to the bottom of the sluice with great rapidity and resists transportation with extraordinary tenacity.

Wright (*Gold Fields and Mineral Districts of Victoria, R. B. Smyth*) says that in a 12-in. sluice sloped 1 in 48, using 600 g.p.m., 95% of the gold was found within 3 ft. of the feed point, lying on a smooth board. *Bowie* states that at NORTH BLOOMFIELD 92% of the total yield was made in the first 1,800 ft. of sluice, 3.75% in 6,200 ft. of bedrock sluice following, 2.5% in undercurrents. He gives considerable detailed data of similar import. Purington (*Bul. 263 USGS 142*) gives the following data: South Coast region of ALASKA, gold bright and rough though fine, mercury used in boxes, 75% saved in the first 600 ft. MCKEE CREEK, Atlin, B. C., slope 0.67 in. per ft., block riffles, gold coarse, 85% saved in first box, all that it pays to clean up saved in the first five boxes (60 ft.) At another mine in the district no gold is caught beyond the first 250 ft. of boxes. ELDORADO COUNTY, CALIF., slope 1.1 in. per ft., car-wheel riffles, mercury in the boxes; 75% of the total recovery was made in the first foot, 8.4% in the next 10 ft., 9.6% in the next 50 ft., and 2% in the next 60 ft.; slightly less than 5% of the total gold recovered was caught in 2,380 ft. of rock-paved sluice following the first 1,000 ft. BONANZA CREEK, KLONDIKE, gold fine, bright, and smooth, 2-ft. boxes on 1-in.-per-ft. grade, block-riffled, 80% of total gold recovery was made in the first box, 85% in the first 180 ft., none in the last two boxes

in the 500-ft. string. Hutchins (*Bul. 263 USGS 190*) estimates that in small-scale Alaskan practice, shoveling-in to short strings (3 to 6) of 12-in. boxes set on about 0.5-in.-per-ft. slope, using pole riffles, about 80 to 90% of the gold fed is recovered but that most fine gold is lost. Bouery (*95 J 1056*) gives the data shown in Table 4 representing the distribution of gold in size and quantity along the

Table 90a. Distribution of gold according to size in La Grange sluice boxes (*After Bouery*)

Box. No.	>10-m.	10~50-m.	50~100-m.	100~150-m.	150~200-m.	<200-m.
5	45.80 oz.	50.70 oz.	1.38 oz.	0.36 oz.	0.31 oz.	1.45 oz.
6–16 incl.	18.00	83.30	2.33	1.00	0.31	0.83
22	1.73	20.22	3.08	0.70	0.25	0.62
48	0.18	2.18	1.06	0.12	0.05	0.16
88	0.018	0.12	0.47	0.008	0.026	0.005
136	None	0.053	0.027	0.043	0.011	0.01

La Grange sluice line. The table indicates remarkable horizontal travel of some of the coarse gold and probable lack of economy, from a gold-saving standpoint alone, in maintaining so long a string of boxes. It also indicates that only the more rounded grains of gold finer than 200-m. are saved and that most of those grains too small to settle in the early boxes do not settle at all.

Capacity. A string of 12-in. Alaskan boxes rarely handles more than 150 cyd. per 10 hr., but this is done easily if sufficient water is available. (*100 J 994, 122 P 417.*) Purington (*Bul. 263 USGS 142*) gives the following figures on Alaskan practice: In the South-Coast region a sluice 4 ft. wide × 4 ft. 10 in. deep, slope 0.33 i.p.f., paved with block riffles handled 5,000 cyd. of gravel and 200,000 cyd. of water per 24 hr. Atlin District (B. C.), 400 cyd. per 24 hr. of coarse heavy gravel were handled with 32,000 cyd. of water in a sluice 24 in. wide, 1,400 ft. long, slope 0.5 i.p.f., with block and rail riffles. Klondike bench gravel, 1,000 cyd. of gravel with 20,000 cyd. of water in a sluice 24 in. wide, 20 in. deep, slope 1 i.p.f., block-riffled.

At Y-Water in Australia sluices for treating tin gravels at the rate of 100 cyd. per hr. are four in parallel, each 10 ft. wide by 3 ft. deep by 180 ft. long. The area of sluices on Australian tin dredges ranges from 8 to 43 sq. ft. per cyd. treated per hr., all late installations ranging between 30 and the higher figure. The corresponding figure on gold dredges is about 23 sq. ft. in Australian practice and 37.5 sq. ft. in English practice (*16 MM 81*). Purington and Smith (*15 MM 148*) state that a Russian sluice 29 in. wide, 18 in. deep, and 280 ft. long, sloped 14 in. in 12 ft., fitted with T-grate riffles and inverted rails set both longitudinally and transversely in different sections, treated 1,100 cyd. (place measure) per 18 hr. and made 96% recovery, 88.3% being made in the first third. *Van Wagenen* gives figures of 100 to 200 cyd. of ordinary gravel or 60 to 80 cyd. of cemented gravel per man per 10 hr., but this is for sluice-box operators only and does not include delivery of material to the boxes. Hutchins (*Bul. 263 USGS 190*) gives about 5.5 cyd. per man shift when shoveling-in and Purington's figures for the same operation range from 2.75 cyd. per 10 hr., where large boulders interfered, to as high as 12 cyd. with 3-ft. bank and 5-ft. lift.

Recovery. Purington estimates (*Bul. 263 USGS*) that even with the coarse gold prevailing in Alaskan deposits, recovery is, at best, 80 to 90% in simple boxes with no undercurrents; that the average for small operations is 70 to 80%, and that 50% is not uncommon, especially with tough, sticky clay, balls of which hold gold, and rob the riffles of gold and amalgam.

Use of mercury in sluices is local rather than general custom. Use is relatively rare in Alaska and was relatively common in California. This probably followed from the character of the gold, which while perhaps as fine in Alaska deposits as in California, was granular, while the fine California gold was scaly and bright and mercury was both necessary and highly effective. Hutchins (*Bul. 263 USGS 204*) recommends its use wherever fine gold that will amalgamate is present. In sluices it is usually added only in the first two or three boxes, rarely to the first quarter or half of the string. It is commonly used on undercurrents and tables. The finer feed is not so liable to splash it out of the riffles and flour it as the coarse gravel in main sluices and the short length of these devices demands the aid of mercury to keep down the values in the tailing.

Mercury is usually introduced after the riffles have sanded up. It should be put in in such a way as to minimize flouring and in an amount insufficient to flood the riffles. The endeavor should be to maintain as large and as clean a surface of mercury as possible without causing excessive travel along the sluice. In some plants mercury is not introduced until just before the clean-up, in which case its purpose is not so much the recovery of gold as aid in collecting it. A low-grade gold analgam (mercury containing a small amount of gold) is more effective than clean mercury.

The quantity used, according to *Bowie*, is about 3 flasks (225 lb.) in the upper 200 to 300 ft. of a 6-ft. sluice. A 24-ft. undercurrent will require 80 to 90 lb. For price range see Sec. 2, Art. 21. In 5- or 10-lb. lots quoted market prices may be more than doubled. Loss ranges from 5 to 10% under best conditions to as much as 25% with steep grades, heavy gravel, leaky sluices, or when clay or organic materials induce flouring. Fouled mercury loses its collecting activity. Straining through chamois, washing with cyanide solution or grease solvents, or retorting are the usual methods of cleaning, listed in order of increasing effectiveness. Common practice on dredge tables ranges from 1/10 to 1/4 lb. per sq. ft. (*IC 6787*).

Loss of mercury depends principally on the quantity used, the character of the gravel, the type of riffles, and the intervals between clean-ups. *Bowie* gives the loss at La Grange as 0.00024 lb. per cyd. He states that at North Bloomfield it was 11 to 25% of the total used and was greatest in the rock sluices, which were cleaned only at long intervals. At the same mine, with light gravel, low slope, and little water the loss was from 4.4 to 6.1%.

Costs. Williams (*56 MM 218*) gives 30¢ per cyd. for shoveling-in operation in easy ground to $1 in tough ground; for group sluicing (distribution of water by pump to a number of elevated single sluices set to suit the requirements of different patches of ground), 30 to 35¢ per cyd.; minimum workable value of ground for such operation, 55¢ per cyd. Costs at large mines with mechanical or hydraulic means for loading the sluice are much lower (see Sec. 2, Art. 20).

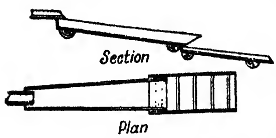

FIG. 73. Long tom (*after Bowie*).

Long tom (Fig. 73) is a small sluice with greater capacity than a rocker but it requires more water. It consists of a sloping trough about 12 ft. long, 15 to 20 in. wide at the upper end, flaring to 24 or 30 in. at the lower end, with sides 8 to 12 in. high. A perforated plate with $^3/_8$- or $^1/_2$-in. holes, set level or slightly inclined, is fitted at the lower end. The usual slope of the trough is 1 to 1 $^1/_2$ i.p.f. Slopes of 3 to 4 i.p.f. are used for fine beach sands in Alaska. A wider and usually shorter trough with transversely riffled bottom, set on a flatter slope, follows the first and receives the undersize from the screen.

Manipulation. Gravel is shoveled into the upper trough and water is led in by a flume at the head end. The operator works the gravel over thoroughly, forks out the boulders, and works fine material through the screen. Coarse gold settles in the upper box, and fine gold is caught behind the riffles in the lower trough. *Wilson* recommends that the slope of the riffled box should be so flat that fine mud will collect therein, thus insuring that fine gold is not scoured out, but this will result in sanding behind the riffle cleats to such an extent that their protective function for fine gold is defeated and the bottom will become merely a transversely undulating sandy surface.

Capacity varies with the kind of gravel and size of screen perforations and is limited by what a man can work through the screen. *Wilson* states it to be 6 cyd. of ordinary light gravel or 3 to 4 cyd. of cemented gravel per 10 hr. with 2 men working, one shoveling in and taking care of tailing and the other working the upper box. *Van Wagenen* gives 5 to 6 cyd. of ordinary gravel or 3 to 5 cyd. of cemented gravel per man per 10 hr., but this is undoubtedly too high.
